Some evidence has shown that in the presence of organic acids, mainly short-chain fatty acids such as acetic, butyric, and propionic acids, there is significant increased growth of gut mucosa. Butyric acid, the metabolic product of *Lactobacillus*, is one of the representatives of organic acids that could potentially be used as alternative growth promoters. Butyric acid exerts multiple effects on the intestinal function of both animals and humans, including acting as a vital energy source for intestinal cells, stimulating epithelial cell proliferation and differentiation (Dalmasso *et al.*, 2008), and inducing antiinflammatory effects (Hodin, 2000). In addition, by stimulating the expression of tight junction proteins and the production of antimicrobial peptides in mucosa, butyric acids are also able to strengthen the gut mucosal barrier (Schauber *et al.*, 2003; Bordin *et al.*, 2004; Peng *et al.*, 2007).

Bioactive phytochemicals

A variety of plant-derived agents are employed worldwide as feed additives in farm animals. As a substitute for antibiotics, these plant-derived compounds also exert production-enhancing effects, including the improvement of dairy weight gain, enhancement of feed conversion efficiency, and increasing milk and egg production (Halldor, 2012). As the secondary metabolites of flowering plants, essential oils have been used as nonantibiotic antimicrobials as animal feed additives for the purpose of both growth stimulation and bacterial inhibition (Hammer and Carson, 2011). Para-thymol, an isomeride of thymol, with higher antibacterial activity and lower volatility, has been found to be safer and exerts even better growth-promoting effects than thymol and carvacrol (Peng *et al.*, 2011). Other bioactive phytochemicals patented worldwide include isoflavone, produced by *Fabaceae* family, diaryheptanoid from the bark of the Japanese shrub alder *Alnus pendula*, *Curcuma aromatica* Salisb extracted from ginger, saponin extracted from yucca, alkaloids from plume poppy, and lignocellulose obtained from *Magnolia*, all of which have been claimed to effectively modulate gut microflora, improve immune function, and promote both absorption and digestion of nutrients by livestock and poultry (Halldor, 2012).

Antimicrobials for Pre-harvest Foodborne Pathogens Reduction in Food Animals

According to the Centers for Disease Control and Prevention (CDC), an estimated 48 million illnesses, 128 000 hospitalizations, and 3000 deaths are caused by foodborne pathogens annually (Centers for Disease Control and Prevention, 2012). Zoonotic pathogens colonized in the gastrointestinal tract of food animals can be shed in feces. Fecal contents play a significant role in carcass cross-contamination and are likely to reach consumers and food processors. In addition, fecal content is a direct source for pathogens in water, soil, vectors, and crops. As a consequence, it remains a major public health concern to reduce the foodborne pathogenic bacteria populations at the farm level. A broad range of preharvest intervention strategies have been employed, and some are still under development. Owing to increased worldwide concern about the transmission of antibiotic resistance from farm animals to humans, the preharvest use of antibiotics has been limited and even gradually prohibited. Though the reduced preslaughter use of antibiotics to reduce foodborne pathogens in farm animals has been partially offset by an increased use of

prescribed antibiotics for therapeutic purposes, the direct use of several common antibiotics and alternative natural antimicrobial agents as a substitute for antibiotics is urgently needed. Major potential natural strategies include using bacteriocin, vaccination, introducing bacteriophages, adding enzymes or organic acids as feed supplements, and the enhancement of competition by introducing substrate-adapted competitive products such as probiotics and prebiotics. Parallel and simultaneous application of more than one preharvest strategy could be a promising strategy to synergistically lower the incidence of foodborne illness.

Selected Antibiotics Registered for Preslaughter Use in Agricultural Animals

Foodborne illness is a significant factor contributing to mortality and morbidity not only in the United States but throughout the world. Various agents such as viruses, bacteria, fungi, and parasites are responsible for more than 200 known foodborne diseases. Among the numerous and various threats, *Salmonella*, *Escherichia coli* O157:H7 (EHEC), *Campylobacter*, and *Listeria* are the leading causes of meat products–related illness and deaths in the United States. Most of these foodborne pathogens are able to live on the skin or in the gastrointestinal tract of food animals such as cattle, swine, sheep, and poultry, especially chickens and turkeys, and in the farm environment where the soil is fertilized with composted animal manure (D'Aoust *et al.*, 2008; Meng *et al.*, 2008; Nachamkin, 2008; Swaminathan *et al.*, 2008). Thus, antibiotics have been widely employed in preharvest use in farm animals and in humans to reduce foodborne pathogens and to prevent foodborne illness. In spite of the widespread use of antibiotics in animals, it is often difficult to choose a specific antibiotic which could target specific pathogens because the microbes usually fall into diverse groups. As a result, broad-spectrum antibiotics are usually employed in preharvest animals. Based on recent research, antibiotic treatment for controlling gastrointestinal pathogens has been found to disrupt the gut microbial ecosystem and thus impair animal health, meat or milk production, and even food safety. Despite the potential shortcomings of antibiotic preharvest treatment, recent research at the farm animal level has shown that antibiotics do have the potential to kill foodborne pathogens inside the body and thus improve food safety.

Most of the antibiotics are routinely administered through animal diets to exert their antimicrobial activities. For example, monensin, one antibiotic in the ionophore class, which might not induce or increase antibiotic resistance and is also not therapeutically used in humans, is approved for use in food animals in the preharvest reduction of foodborne pathogenic bacterial populations.

Poultry

Antibiotics have been put into widespread use in poultry farms for disease prevention and treatment since the 1940s. Campylobacteriosis in humans is frequently acquired via the consumption of undercooked poultry meat contaminated with *Campylobacter jejuni*, identified and isolated from multiple farm animals but most commonly in poultry meat products (Vugia *et al.*, 2007). Effective antibiotics such as erythromycin can be administered in feed or drinking water. Because fluoroquinolones and erythromycins belong to the classes of antimicrobials, these are also used in human campylobacteriosis treatment. The preharvest use of these two antibiotics in poultry needs to be carefully evaluated. Some researchers have pointed out that *Campylobacter* is resistant to macrolides and fluoroquinolones due to the inappropriate use of these antibiotics (Nachamkin, 2008).

Human listeriosis is caused by infections of the bacterium *Listeria monocytogenes*, which result from the consumption of contaminated poultry or ready-to-eat poultry products. Its resistance to many commonly used antibiotics makes treatment of *L. monocytogenes* more difficult. However, a study has found that pediocin and enterocin were more active against *L.monocytogenes* than nisin (Cintas *et al.*, 1998).

Colonization by *Salmonella enterica* serovars Enteritidis and Typhimurium in poultry is relatively common and a major public health concern. Transmission of enteric salmonellosis to humans usually occurs through consumption of contaminated poultry and poultry products, specifically eggs. Owing to the presence of multiple antibiotic-resistant strains of *Salmonella*, antibiotic treatment against this pathogen has been compromised at least to some extent. One major concern is the strain of *Salmonella enterica* serovar Typhimurium (DT104) commonly found in poultry and eggs. DT104 is demonstrated to be resistant to at least five antibiotics – ampicillin, chloramphenicol, streptomycin, sulfonamides, and tetracycline. Preharvest control of DT104 continues to be a significant challenge due to its increased virulence by alterations of inherent pathogenic characteristics and treatment failures resulting from the inappropriate use of antibiotics (Besser *et al.*, 2000). However, combined use of trimethoprim and sulfonamide at the preharvest level might be effective in reducing *Salmonella* in chicken gut. Other possible choices include fluoroquinolones and the third-generation cephalosporins (D'Aoust *et al.*, 2008); **Table 2** shows the preslaughter FDA-approved antibiotics commonly used in the poultry industry (Teshome *et al.*, 2007).

Cattle

EHEC causes infection and various diseases, especially hemorrhagic colitis, in humans with a relatively low infectious dose (Lee and Greig, 2010). EHEC is mainly harbored in the gastrointestinal tracts of healthy cattle and is shed in their feces. The major source of EHEC was traced to ruminant manure, but undeniably, EHEC was also identified in some nonruminant farm animals including swine and fowl due to the cross-contamination spread by ruminant manure. But, since bovine manure is the major source of EHEC contamination in the farm environment and animal meat products, effective preharvest control targeting reduced prevalence and quantity of fecal EHEC excretion by live cattle is crucial. EHEC does not typically exhibit the drug resistance to the use of multiple antibiotics which is frequently found in enteropathogenic *E. coli* and other foodborne pathogens like *Campylobacter* and *Salmonella*, though the use of ionophores does not show significant influence on the prevalence of EHEC (Edrington *et al.*, 2003; LeJeune and Kauffman, 2006). However, it has been shown that almost all EHEC isolates are

Table 2 FDA-approved antibiotics for preharvest subtherapeutic purpose in poultry

Antibiotics	*Dosage in feed (mg head^{-1} day^{-1})*	*Main treatment purpose*	*Withdrawal time (days)*
Arsanilic acid	75–120	Feed efficiency and growth	5
Avilamycin	5–10	Feed efficiency and growth	None
Avoparcin	7.5–15	Feed efficiency and growth	None
Bacitracin	4–50	Feed efficiency and growth	None
Bambermycins	1–20	Feed efficiency and growth	None
Chlortetracycline	10–100	Disease control	None
Lincomycin	2–4	Feed efficiency and growth	None
Oxytetracycline	5–50	Disease control	0–3
Penicillin	2–50	Feed efficiency and growth	None
Roxarsone	23–46	Feed efficiency and growth	None
Spiramycin	5–20	Feed efficiency and growth	None
Avoparcin	7.5–15	Feed efficiency and growth	None
Tylosin	10–110	Feed efficiency, growth, and disease control	None
Virginiamycin	>25	Disease control	None

Table 3 FDA-approved antibiotics for preharvest subtherapeutic use in cattle

Antibiotics	*Dosage in feed (mg head^{-1} day^{-1})*	*Main treatment purpose*	*Withdrawal time (days)*
Bacitracin zinc	35–70	Feed efficiency and growth	None
Bambermycins	1–5	Growth	None
Chlortetracytcline	350	Disease control	2
Laidlomycin	5–10	Feed efficiency and growth	None
Lasalocid	10–30	Feed efficiency and growth	None
Monensin	5–30	Growth and Disease control	None
Oxytetracycline	75	Disease control	None
Tylosin	8–10	Disease control	None
Virginiamycin	10–25	Disease control	None

susceptible to neomycin sulfate (Mora *et al.*, 2005). Neomycin sulfate is an approved antibiotic used in cattle, where it has been demonstrated to significantly decrease the fecal excretion of EHEC (Elder *et al.*, 2002; Woerner *et al.*, 2006). Given appropriate use and quick withdrawal, neomycin appears to be a promising candidate for preharvest use in the cattle industry. **Table 3** shows the commonly used FDA-approved preslaughter antibiotics in the cattle industry (Teshome *et al.*, 2007).

Swine

Antibiotics and other antimicrobial agents have been widely used as preharvest feed additives in the swine industry since the early 1950s. In addition to effectively stimulating swine growth rates and improving reproductive performance, preharvest use of antibiotics is also able to reduce the populations of foodborne pathogens including *Campylobacte*r, EHEC, *Listeria*, and *Salmonella*. Currently, preslaughter use of carbadox, cephalosporins, lincosamides, macrolides, penicillins, pleuromutilins, polypeptides, quinolones, sulfonamides, and tetracyclines is cleared by the Food and Drug Administration in swine feed (Morrison, 2001). Among these approved antibiotics, the feeding of chlortetracycline and tylosin decreased fecal shedding in swine artificially infected with EHEC, and the feeding of spectinomycin in pigs under 4 weeks old and weighing less than 15 lb effectively controlled the infectious bacterial enteritis caused by *E. coli* and salmonella (Friendship, 2006). However, bacitracin did not exert significant antimicrobial effects on EHEC (Irwin *et al.*, 2003). **Table 4** shows the commonly used FDA-approved preslaughter antibiotics in the swine industry (Teshome *et al.*, 2007).

Nonantibiotic Antimicrobials Used in Preharvest Reduction of Foodborne Pathogens in Farm Animals

Because of the increased concern among consumers about antibiotic resistance, several nonantibiotic antimicrobials have been developed and introduced for use by farmers to inhibit preharvest foodborne pathogens. The major potential agents include bacteriocin, bacteriophages, chlorate, vaccines, organic acids, and other plant- or animal-derived products. Some of their advantages and disadvantages will be discussed in this part.

Bacteriocins

Bacteriocins are proteins or peptides with antimicrobial activities produced by certain bacteria for the purpose of inhibiting the growth of their competitive bacterial strains in the environment. Such antimicrobial proteins are able to inhibit the growth of several major foodborne pathogens including EHEC, *Salmonella*, and *Listeria* (Stahl *et al.*, 2004; Patton *et al.*,

Table 4 FDA-approved antibiotics for preharvest subtherapeutic use in swine

Antibiotics	*Dosage in feed (mg head^{-1} day^{-1})*	*Main treatment purpose*	*Withdrawal time (days)*
Apramycin	150	Disease control	28
Arsanilic acid	45–90	Feed efficiency and growth	5
Bacitracin methylene disalicyrate	10–30	Feed efficiency and growth	None
Bacitracin zinc	20–40	Feed efficiency	None
Bambermycins	2–4	Growth	None
Carbadox	50	Disease control	42
Chlortetracycline	>50	Disease control	None
Lincomycin	40–200	Disease control	None
Oxytetracycline	22	Disease control	5
Penicillin	10–50	Feed efficiency and growth	None
Roxarsone	182	Disease control	5
Tiamulin hydrogen fumerate	35–200	Disease control	2–7
Tilmicosin	181–363	Disease control	7
Tylosin	10–110	Feed efficiency, growth, and disease control	None
Virginiamycin	>25	Disease control	None

2007). The application of bacteriocin isolated from *Lactobacillus salivarius* and *Paenibacillus polymyxa* in chicken intestinal tracts has been shown to induce a dramatic reduction in broiler chicken cecal *Campylobacter* colonization (Svetoch and Stern, 2010). Nisin has already been found to be effective in spoilage bacteria reduction in meat and milk, and encapsulated nisin is able to inhibit the growth of *L. monocytogenes* (da Silva Malheiros *et al.*, 2010), although nisin's preharvest application is still under research. However, under the basic principle of bacteriocin, by protecting bacteriocins from ruminal or gastric degradation, once reaching the lower gut, bacteriocins exert their antimicrobial activities by disrupting the cell membranes of target foodborne pathogens. Owing to their nontoxic characteristics on eukaryotic host cells, bacteriocins are considered safe for consumption of meat and meat products.

Bacteriophages

Because they are highly specific in recognizing and injecting 'disrupting DNA' into a host bacterium, bacteriophages can be active against specific bacterial strains. Specificity allows bacteriophages to be used against targeted foodborne pathogens in a mixed population without disturbing the composition of normal gut microflora. In 2007, a phage spray produced by Omnilytics (Salt Lake City, UT), specifically against EHEC in preharvest live cattle, was approved by the FDA. Other studies have also tested the short-term reduction of *Salmonella* colonization in poultry and swine (Callaway *et al.*, 2008). Several researchers have also tested the oral consumption of large doses of bacteriophages and found it to be harmless to animals. Owing to their rapid replication and high level of specificity, bacteriophages can serve as a potential preharvest strategy against foodborne pathogens in agricultural animals. However, the efficacy of bacteriophages against infecting bacteria should be tested in the lab before application. The specificity of bacteriophages is also a disadvantage when a need to target multiple pathogens or causative agents of disease is not confirmed (Inal, 2003). In addition, compared to antibiotics, bacteriophages are more complex organisms that are able to transfer genes between bacteria and induce pathogenic mutation. Only by careful selection of strictly lytic bacteriophages and sequencing their hereditary materials can cross-gene transfer be prevented (Inal, 2003). In comparison with antibiotics, the administration of bacteriophages requires trained personnel, which makes the application of bacteriophages much more difficult for farmers.

Chlorate

Chlorate is the analog of nitrate reductase, both of which can catalyze the conversion from nitrate to nitrite for the anaerobic respiration of *Salmonella* and *E. coli*. The accumulation of chlorite, degraded from chlorate, in the cytoplasm is able to kill bacteria (Stewart, 1988). Some studies have demonstrated that chlorate administered in drinking water significantly reduces EHEC populations in both cattle and sheep in the rumen, intestine, cecum, and feces (Callaway *et al.*, 2003). In addition, preliminary studies examining the use of chlorate in broilers and in turkeys have also yielded promising results (Byrd *et al.*, 2003; Moore *et al.*, 2006). Addition of chlorate to swine diets reduced experimentally inoculated *Salmonella* and EHEC fecal and intestinal populations (Anderson *et al.*, 2001a, b). Currently, chlorate has been licensed as a product but needs evaluation in its application.

Vaccination

Vaccination is the method of inhibiting pathogens by inducing the defense mechanisms of animals' own immune systems. Some specific vaccination has already shown great efficacy in reducing the levels of foodborne pathogens in agricultural farm animals. Vaccines against *Salmonella* strains have been developed for use in swine and dairy cattle (House *et al.*, 2001). More recently, a vaccine designed to inhibit fecal EHEC in cattle has also been developed (Fox *et al.*, 2009). Based on these research efforts, the use of vaccination in preslaughter reduction of foodborne pathogens seems to hold promise. Vaccines made from any one bacteria serovar cannot confer cross-protection against another serovar, no matter how much antigenic similarity there is between them, but more than 2500 serovars of *Salmonella* are found in animals and humans. *Campylobacter jejuni*, *Campylobacter hyointestinalis*, *Campylobacter*

upsaliensis, *Campylobacter lari*, and *Campylobacter fetus* are also found in farm animals (Singh, 2009). As a consequence, super-high specificity and additional costs prevent vaccination from being commonly used in agriculture.

Other natural antimicrobial agents as feed supplements

Organic acids are gradually being employed in animal nutrition for both their nutritional value and their antimicrobial effects. Organic acids produced by the anaerobic microflora of the large intestine include acetate, lactate, malate, and propionate. Some of them have been shown to exhibit antimicrobial activity against gram-negative bacteria such as EHEC, *Salmonella*, and *Campylobacter* (Huyghebaert *et al.*, 2011).

Various plant products can also serve as antimicrobial agents. For example, pasteurized blueberry juices have been shown to have antimicrobial effects on multiple major foodborne pathogens such as *Salmonella* Typhimurium, *C. jejuni*, *L. monocytogenes*, and EHEC (Biswas *et al.*, 2012). Other organics such as cocoa, peanut skin, and the pomace of blueberry and blackberry have also shown antimicrobial activity but need further study. Multiple fruits and vegetables contain phenolic compounds, such as lignins and tannins, both of which are able to affect the gastrointestinal tract via antimicrobial activity (Cueva *et al.*, 2010). Tannins have been found to significantly reduce the population of EHEC in cattle (Wang *et al.*, 2009). Another study showed that highly lignified forages could reduce the shedding period of EHEC (Wells *et al.*, 2005). In addition, most of the essential oils such as citrus oil usually exert their antimicrobial effects by disrupting the cell membrane of bacteria (Turgis *et al.*, 2009). As a result, both organic acids and bioactive phytochemicals have been proposed as potential preharvest agents against foodborne pathogens in farm animals.

Multiple animal-derived products have also been documented as being effective in foodborne-pathogen inhibition. Chitosan, isolated from the exoskeletons of crustaceans and arthropods (insects, spiders, millipedes, and centipedes), has been shown to inhibit the growth and reduce trans-shell penetration of mold and several foodborne pathogens including *S.* Enteritidis, *E. coli*, and *L. monocytogenes* (Leleu *et al.*, 2011). A heat-stable and salt-tolerant peptide, pleurocidin, could be isolated from myeloid cells and mucosal tissue of both vertebrates and invertebrates, whose inhibitory effect against different foodborne pathogens such as *L. monocytogenes* and EHEC has already been documented (Jung *et al.*, 2007). Other products such as defensin, lactoferrin, lactoperoxidase, lysozyme, and ovotransferrin have all shown their potential in meat or the preservation of milk products and in reducing multiple foodborne pathogens, but their application in preharvest control of foodborne pathogens in farm animals needs to be studied further.

Antibiotics Used as Veterinary Medicine

The therapeutic treatment of individual sick animals with antibiotics or other effective antimicrobials is essential and is employed all over the world. In 2007, global sales of animal health products included: Western Europe (US$110 million), North America (US$725 million), the Far East (US$435 million), Latin America (US$275 million), Eastern Europe (US $150 million), and the rest of world (US$80 million) (Evans *et al.*, 2008). Antibiotics used for veterinary therapy are often administered orally through feed and water, or by injection, in order to relieve animals' suffering and reduce production losses. However, if certain livestock or poultry are sick, the whole herd or flock needs to be treated to prevent the spread of disease. In these cases, antibiotic treatment is usually given in high doses, intermittently within a relatively short period of time. Broad-spectrum or combinations of antibiotics are commonly used in such situations when the specific pathogens of concern are unidentified or in doubt. Worldwide estimated sales of antibiotic products in 2007 include macrolides (US$629 million, 22.7%), penicillins (US$550 million, 19.8%), tetracyclines (US$533 million, 19.2%), quinolones (US$531 million, 19.1%), and sulphonamides (US $118 million, 4.3%), with the leading products being oxytetracycline (US$272 million), enrofloxacin (US$259 million), chlortetracycline (US$257 million), ceftiofur (US$200 million), florfenicol (US$114 million), and tulathromycin (US $90 million) (Evans *et al.*, 2008). However, a narrow-spectrum antibiotic able to target a specific pathogen involved in animal disease should be the first choice and could also lower the risk level of antibiotic resistance. The major animal diseases requiring therapeutic use of antibiotics are respiratory and enteric diseases in calves and pigs, necrotic enteritis in poultry, and mastitis in dairy cattle.

Approved Antibiotics against Livestock Diseases

Antibiotics are commonly used therapeutically against a broad range of infectious diseases in livestock, including cattle, pigs, sheep, and horses, but currently treatment using antibiotics is becoming more pathogen-specific under the supervision of veterinarians. There are three major therapeutic patterns of antibiotic use in livestock: prophylaxis, which targets exposed healthy animals before onset of risk diseases; metaphylaxis, which is the mass treatment of animal populations currently suffering from diseases before the onset of blatant illness; and treatment for animals experiencing acute clinical diseases. The dose regimen for these three therapeutic uses of antibiotics relies on the expected minimum inhibitory concentration of the target pathogens expected to be implicated.

Three of the most prevalent infectious diseases in livestock are respiratory disease, enteric disease, and mastitis (Giguère *et al.*, 2006; Radostits *et al.*, 2007; Zimmerman *et al.*, 2012).

Mannheimia, *Pasteurella*, and *Haemophilus* are three major pathogens responsible for respiratory disease in cattle, and they constitute one of the biggest health challenges for dairy cattle (Barrett, 2000; Rerat *et al.*, 2012). Tetracyclines, especially chlortetracycline and oxytetracycline, are commonly added to feed and water to treat cattle respiratory disease (Apley and Coetzee, 2006). Other approved antibiotics for bovine respiratory disease treatment include aminoglycosides, especially spectinomycin and neomycin, macrolides in the form of tilmicosin and erythromycin, tylosin, penicillins (amoxicillin and ampicillin), cephalosporin especially ceftiofur, and sulfonamides (sulfamethazine and sulfadimethoxine). Besides

these, florfenicol and enrofloxacin are also approved by the FDA (Apley, 2001).

Apart from respiratory disease, enteric disease involving *E. coli* and *Salmonella* is also common in livestock. Neomycin, in the aminoglycoside class, is commonly used as a water additive against these enteric disease. Chlortetracycline and oxytetracycline under the tetracycline class are also approved by the FDA for the treatment of these enteric bacterial pathogens (Apley, 2001). Infectious agents include rotavirus, coronavirus, and cryptosporidium, for which antimicrobials are still under research.

Mastitis is a major problem in dairy cattle and can impair normal lactation. Pathogens including *Pseudomonas*, *Staphylococcus*, *Mycoplasma*, *Pasteurella*, *E. coli*, and *Streptococcus* cause mastitis (Kandasamy *et al.*, 2011). Novobiocin, pirlimycin, and streptomycin are FDA-approved therapeutics for treatment of mastitis. Any of these antibiotics can be used alone or in combination with penicillin (Wagner and Erskine, 2006). Other approved intramammary antibiotics against mastitis are amoxicillin, cephapirin, cloxacillin, hetacillin, and lincomycin (Wagner and Erskine, 2006). Erythromycin is also approved by the FDA in the form of an injectable antibiotic. In addition to these, beta-lactams, cephalosporins, neomycin, and tetracyclines are also recommended.

In addition to these three major livestock diseases, footrot, metritis, pleuropneumonia, and colitis are also common in farm animals. In the case of footrot (infectious pododermatitis), ceftiofur, injectable oxytetracyclines, tylosin, erythromycin, and trimethoprim-sulfonamide combinations are FDA-approved antibiotics. Metritis is also a common disease in dairy cows. Tylosin and injectable oxytetracycline are the only two products approved by the FDA for the treatment of metritis. Procaine penicillin, amoxycillin, tetracyclines, trimethoprim, and tilmicosin are usually used for treatment of pleuropneumonia in swine (Constable *et al.*, 2008). For colitis, caused by *Serpulina*, dimetridazole, tiamulin, and lincomycin are three common antibiotics being used currently (Friendship, 2006; Burch *et al.*, 2008). For effective control of lactic acidosis in the lambs, virginiamycin is used as a feed additive, though therapeutic use of antibiotics is relatively rare in sheep or goat production due to the high cost. For horses, gentamicin is injected routinely for foal sepsis, whereas virginiamycin is given in feed against laminitis (Apley, 2001).

Approved Antibiotics against Poultry Diseases

Since the 1940s, antibiotics have also been used in poultry farming for both therapeutic and prophylactic purposes. But due to recent improvements in husbandry, hygiene conditions, and farm management, bacterial diseases in poultry have been better controlled with less reliance on antibiotics. However, antibiotic therapy is still useful and required when alternative disease control methods such as vaccination fail. Important and common poultry diseases include necrotic enteritis, chronic respiratory diseases, gangrenous dermatitis, fowl cholera, and avian influenza (Pattison, 2008; Saif *et al.*, 2008). Antibiotic treatments for these diseases are predominantly done through supplementation in either water or feed. Most of the effective and common antibiotics are being used as therapeutic intervention in poultry diseases (Hofacre, 2006).

Necrotic enteritis is the most common infectious disease in modern poultry farms and can result in huge financial losses. *Clostridium perfringens* is the major causative bacteria of necrotic enteritis. However, the occurrence of this disease is always associcated with the outbreak coccidial infection, which induces the gut to be more susceptible to *C. perfringens* (Dahiya *et al.*, 2006). Tetracycline, streptomycin, neomycin, bacitracin, and avilamycin in feed are the four most common antibiotics targeting necrotic enteritis (Wages, 2001). Control of *C. perfringens* infection together with prevention of coccidiosis could be accomplished by adding antibiotics such as virginiamycin (20 g ton^{-1}), bacitracin (50 g ton^{-1}), and lincomycin (2 g ton^{-1}) to feed (Wages, 2001). The ionophore classes of anticoccidial compounds are also effective in preventing coccidial infections. In addition, probiotics administration is also used as an effective method to both prevent and treat clinical necrotic enteritis.

Controlling respiratory disease in poultry is important to ensure maximum economic profits. Respiratory disease in poultry is induced by several complex factors including viral presence, stress, and dietary changes, but *Mycoplasma gallisepticum* infection is responsible for most respiratory diseases in poultry (Animal Health National Program, 2007). A variety of antibiotics such as tylosin, tiamulin, tilmicosin, aivlosin, tetracyclines (mainly doxycycline, chlortetracycline, and oxytetracycline), spiramycin, erythromycin, gentamicin and ketasamycin, neomycin, and colistin are used, both alone and in various combinations, to control and cure respiratory disease in poultry (Loehren *et al.*, 2008). But fluoroquinolones (enrofloxacin, danofloxacin, norfloxacin, flumequin, etc.) are used in the withdrawal phase.

Gangrenous dermatitis is caused by contamination of more than one type of bacteria including *Clostridium septicum*, *Staphylococcus aureus*, and *E. coli* (Li *et al.*, 2010). Owing to the involvement of various bacterial pathogens in gangrenous dermatitis, broader-spectrum antibiotics are needed for the treatment and control of this disease. Preferred effective antibiotics include erythromycin, penicillin, and tetracycline, especially oxytetracycline (Wages, 2001).

Pasteurella multocida is the causal agent of fowl cholera (Siti and Robert, 2000). This contagious bacterial disease usually results in high morbidity and mortality rates. Sulfonamides are commonly used for early treatment (Wages, 2001). Sulfaquinoxaline sodium, together with sulfamethazine and sulfadimethoxine in feed or water, is commonly used to control fowl cholera in poultry (Loehren *et al.*, 2008). Tetracycline and norfloxacin administered via feed and water or administered parenterally are also helpful in controlling fowl cholera. And combination streptomycin-dihydrostreptomycin injection is effective in ducks.

Other useful antibiotics include lincomycin, virginiamycin, spectinomycin, tylosin, and erythromycin, which are mainly used as gram-positive antimicrobials. In addition, gentamicin and ceftiofur are the most commonly used in *in ovo* injectable antibiotics (Loehren *et al.*, 2008). In the case of protozoan diseases, which include coccidiosis caused by *Eimeria* and histomoniasis caused by *Histomonas meleagridis*, coccidiostats and histomonostats in the form of feed additives are used as effective antimicrobials (Wages, 2001).

Limitations of Antibiotic Use in Animals

Antibiotics employed for infectious disease prevention and treatment in large groups of farm animals such as cattle, swine, and chicken are usually administered orally in drinking water or as feed additives, and sometimes also via intramammary infusions. These antibiotics are likely to result in residue in edible tissues such as milk and eggs. Multiple antibiotic residues are harmful during the development of human organs, as well as the nervous and reproductive systems. As a result, infants and young children are most susceptible to these residue compounds because of their weak body protection. By establishing preslaughter withdrawal periods, restricting certain antibiotics used in laying hens, and discarding milk produced after intramammary infusions of antibiotics in lactating animals, these harmful antibiotic residues could be reduced or even eliminated (Page and Gautier, 2012).

Public Health Concerns about Antibiotic Resistance

The use of antibiotics, first introduced in the mid-twentieth century, was considered the single most effective medical strategy for dramatically reducing morbidity and mortality in both humans and animals (Andersson and Hughes, 2010). However, the overuse of antibiotics has caused increased antibiotic resistance among multiple human pathogens. Whether or not the pool of resistance genes generated by use of antibiotics in farm animals has induced the prevalence of failures in therapy for human infectious diseases is compounded by the widespread use of antibiotics in livestock and poultry is still controversial. So far, judging from numerous journal articles, reviews, conference reports, newspapers, and TV reports, the inappropriate use of antibiotic in farm animals and its potential risk to human health have become the greatest public health concern among both consumers and scientists. Governments worldwide have already sought regulatory and legal authority in order to restrict or even abolish the nontherapeutic use of antibiotics (Page and Gautier, 2012).

Conclusion

Antimicrobial substances, especially antibacterial agents, are commonly employed worldwide to improve the performance, health, and production of livestock, dairy cattle, and poultry. These agents are used to protect against illness, help reduce significant agricultural losses, and prevent foodborne infections in humans. For the subtherapeutic use of antimicrobials, preharvest treatment for both promotion of animal growth and inhibition of colonization and cross-contamination of foodborne pathogens have drawn great attention because of the urgency of the situation as well as the effectiveness of antibiotics in human disease treatment. However, some agents used in animal agriculture belong to classes also employed in human medicine, such as macrolides, penicillins, sulphonamides, and tetracyclines. This dual use of antibiotics and the common concern of multiple antibiotic resistance in human pathogens and the potential impact of antibiotic residues in food on public health are controversial and have raised concerns. As a result, efforts to develop alternatives such as plant-derived antimicrobial agents and biopreservatives are underway. Although the thoughtful and measured therapeutic use of antibiotics or other effective antimicrobials is essential to livestock producers, regulatory bodies, and consumers, narrow-spectrum antibiotics remain the first choice, and a comprehensive understanding of the use of narrow-spectrum antibiotics in preharvest-level farm animal production, along with proper guidance from the veterinary profession, are vital to solving this complex issue.

Glossary

Adducts A chemical compound that forms from the addition of two or more substances. The product of an addition reaction.
Bioavailability The degree to which a drug or other substance becomes available to the target tissue after administration.
Carcinogenicity The ability or tendency to produce cancer.
Fatty degeneration The accumulation of fat globules within the cells of an organ, such as the liver or heart, resulting in deterioration of tissue and diminished functioning of the affected organ.
Hyperestrogenism An abnormally high presence of estrogen. Condition characterized by and caused by excessive secretion or intake of estrogen.
Teratogenic Of, relating to, or causing malformations of an embryo or a fetus.
Water activity The ratio between the vapor pressure of a material (p) and the vapor pressure of pure water under the same conditions. Water activity values range from 0 (zero) to 1 (one).

Main Toxigenic Fungi and Mycotoxins

Mycotoxins are organic compounds of low molecular weight, produced as secondary metabolites by several species of fungi, showing various chemical structures (**Figure 1**) and occurring in agricultural commodities, especially in cereal products. Human and animal diseases caused by mycotoxins are called mycotoxicoses, which are diffuse syndromes mainly caused by lesions in organs, such as liver, kidneys, epithelial tissue (skin and mucous membranes), and central nervous system, depending on the type of the toxin (Diaz, 2005).

About 100 000 fungi species have already been identified, from which more than 200 may be considered potentially toxic, but only about 5% are known to produce toxic compounds or classes of compounds that cause adverse effects in animals and humans in different parts of the world (Gompertz *et al.*, 2008). However, the most important mycotoxins are aflatoxins, fumonisins, ochratoxins (OT), zearalenone, and trichothecenes, because of their frequent occurrence in feedstuffs and the high toxigenic potential demonstrated in domestic animals.

Contamination of feedstuffs with toxigenic fungi may occur in different phases of production and processing, from sowing to transportation and storage. Besides, as mycotoxins are generally highly chemically stable, they may remain in feedstuffs even after fungi are removed by usual processing and packaging processes.

Mycotoxicoses may be observed in different animal species, and the symptoms of intoxication vary depending on the type of mycotoxin, as presented in **Table 1**. However, the toxicity of some individual mycotoxins can be enhanced in a synergistic or additive manner when they occur as cocontaminants and are consumed by different animal species (Grenier and Oswald, 2011).

The economic impact of mycotoxins in animal health includes mortality of domestic animals, increased costs with veterinary care, and decreased production efficiency. Acute mycotoxicoses are rare in animal production, and chronic exposure to low levels of mycotoxins is responsible for reduced productivity and increased susceptibility to infectious diseases (Oswald *et al.*, 2005).

Toxigenic Fungi

The name fungi is given to a group of living organisms including microfungi (molds and yeasts) and macrofungi (mushrooms). Filamentous microfungi (molds) are the ones that produce mycotoxins. Yeasts are not known to produce mycotoxins, although they are of considerable interest in the food industry. Unlike plants, fungi do not contain chlorophyll, do not accumulate starch, and do not have cellulose in their cell walls. However, they resemble animal cells for being able to store glycogen, and contain chitin, a polymer that is a glucose derivative. Thus, all fungi live a heterotrophic existence in nature, either as parasites or saprobes, dependent on living or dead organic matter for their nutrients.

There are a number of essential phases in the life of a fungus: spore germination, mycelium vegetative growth, spore-bearing development, spores production, liberation, and dispersal. The reproductive structures of fungi, called spores (propagules), are able to reproduce and generate new cells in favorable environmental conditions. According to their origin, spores can be sexual or asexual. Fungi are classified according to their morphology and chemistry and, more recently, to their molecular biology. One of the most current core features show four groups in the Kingdom fungi: Chytridiomycota, Zygomycota, Basidiomycota, and Ascomycota. Micotoxigenic species are mostly found in the Ascomycota Division; however, mushrooms are found within the Basidiomycota Division (macrofungi), producers of mycetisms.

The main mycotoxin-producing fungi species belong to the genera *Aspergillus*, *Penicillium*, *Fusarium*, *Alternaria*, *Claviceps*, *Myrothecium*, *Stachybotrys*, *Phoma*, *Trichotecium*, *Cephalosporium*, *Trichoderma*, *Cladosporium*, and *Pithomyces*. However, the

 doi:10.1016/B978-0-444-52512-3.00200-X

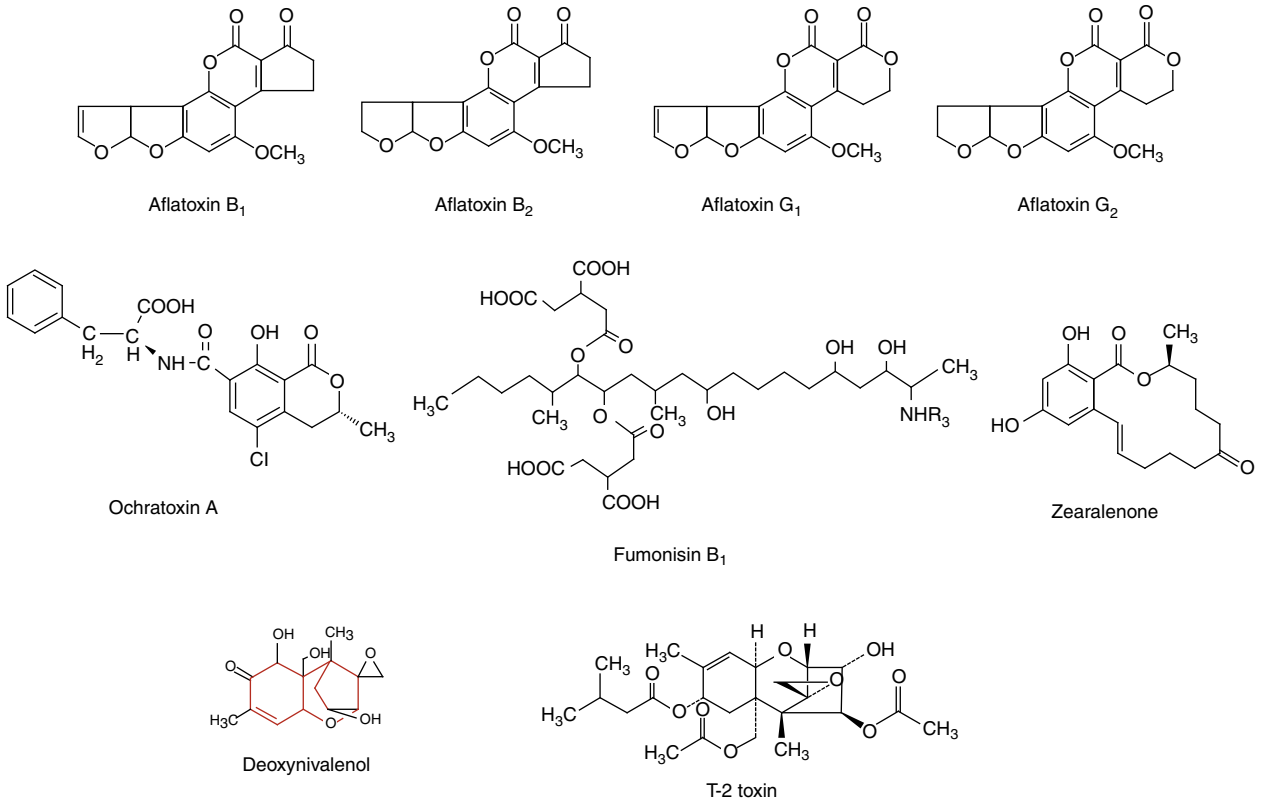

Figure 1 Chemical structures of main mycotoxins.

Table 1 Main toxigenic fungi, mycotoxins, and respective biological effects in susceptible species

Fungi species	*Mycotoxin*	*Biological activity*	*Main susceptible animals*
Aspergillus flavus and *Aspergillus parasiticus*	Aflatoxins	Hepatotoxicity and carcinogenicity	All species
Fusarium graminearum and *Fusarium culmorum*	DON (Vomitoxin)	Dermatotoxicity and immunosuppression	Swine
Fusarium sporotrichioides	Toxin T-2	Alimentary Toxic *Aleucia* (ATA)	Swine and poultry
Fusarium verticillioides	Fumonisins	Leucoencephalomalacea, pulmonary edema, and carcinogenicity	Swine and equine
Penicillium verrucosum and *Aspergillus ochraceus*	Ocratoxin A	Nefrotoxicity	Swine and poultry
Fusarium graminearum	Zearalenone	Estrogenic	Swine and bovine

genera *Aspergillus*, *Penicillium*, and *Fusarium* are considered the most important producers of mycotoxins. In general, these species have worldwide distribution, although some of them are specific to certain countries due to climate differences and local agricultural practices. Microscopic structures of the three genera are illustrated in Figure 2.

The development of toxigenic fungi and mycotoxin production are dependent on complex factors such as: (1) type of substrate; (2) physical factors: water activity, temperature, pH, aeration, and relative humidity; and (3) biological factors: genetic potential to produce mycotoxin, viable spores, presence of insects and mites, fungi interaction, mechanical damage, and storage time (Figure 3). However, humidity and temperature are the most influential factors in mycotoxin production. The water existing in foods is not always available to the fungus. Some substrates strongly retain water, impairing its absorption by the fungus. In others, water may be almost fully available and can be measured for each substrate. This measure is called water activity of the substrate.

The dependence of fungal growth on water availability is variable, with some species growing at water activity from 0.97 to 0.58. The minimum water activity necessary for the growth of the main toxigenic fungi is 0.76, and the minimum water activity for the growth of *Aspergillus flavus* and *Fusarium verticillioides* is 0.78 and 0.87, respectively. It is noteworthy that Aw values for the production of mycotoxins are often higher than those needed for the growth of the producer fungi. Table 2 shows temperatures and minimum water activity requirements for growth and mycotoxin production by the major toxigenic fungi.

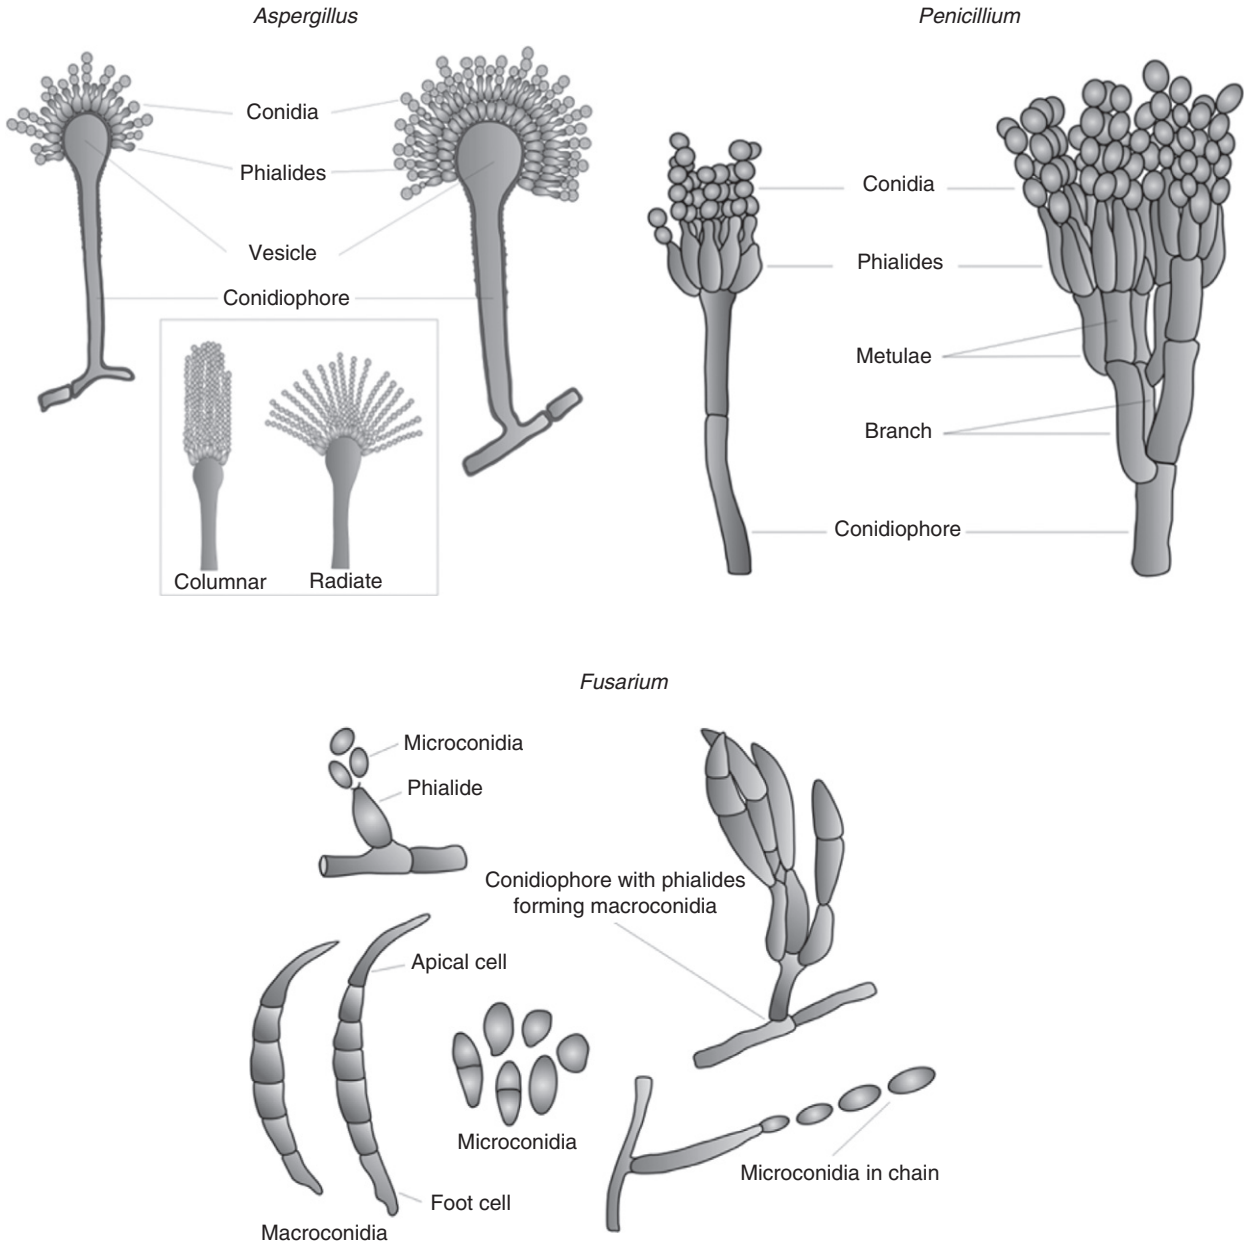

Figure 2 Microscopic structures fungi of genera *Aspergillus*, *Penicillium*, and *Fusarium*.

Toxigenic fungi may be present in food without producing any toxin. Thus, the demonstration of mold contamination is not the same as that of mycotoxin contamination. In relation to aflatoxins, some authors point out that, in average, 50% of isolated strains are producers of aflatoxins in foods (Geisen, 1998). It is noteworthy that the absence of visible signs of mold formation does not necessarily mean that the food is free of toxins, since they can remain in the product even after the fungus disappears. A particular mycotoxin can be produced by more than one species of fungi. For example: aflatoxin can be produced by *A. flavus*, *Aspergillus parasiticus* and *Aspergillus nomius*. The same species of *Fusarium* can produce more than one toxin. Thus, *F. verticillioides* can produce fumonisins, zearalenone, and moniliformin.

Aflatoxins

Aflatoxins are produced by fungi in the genus *Aspergillus*, mainly species *A. flavus* and *A. parasiticus*. These toxins were discovered in 1960, after an outbreak in turkeys in England (Turkey X disease). In this outbreak, thousands of birds died after the intake of Brazilian peanut meal. Nowadays, 20 similar compounds are called aflatoxins, although the most important types are aflatoxins B_1, B_2, G_1, and G_2. Aflatoxin B_1 (AFB_1) is the most frequent type naturally found in cereals, and the one with the greatest toxigenic power, followed by G_1, B_2, and G_2. Aflatoxin M_1 (AFM_1), a detoxification product present in milk as a result of AFB_1 biotransformation, is also as toxic as AFB_1.

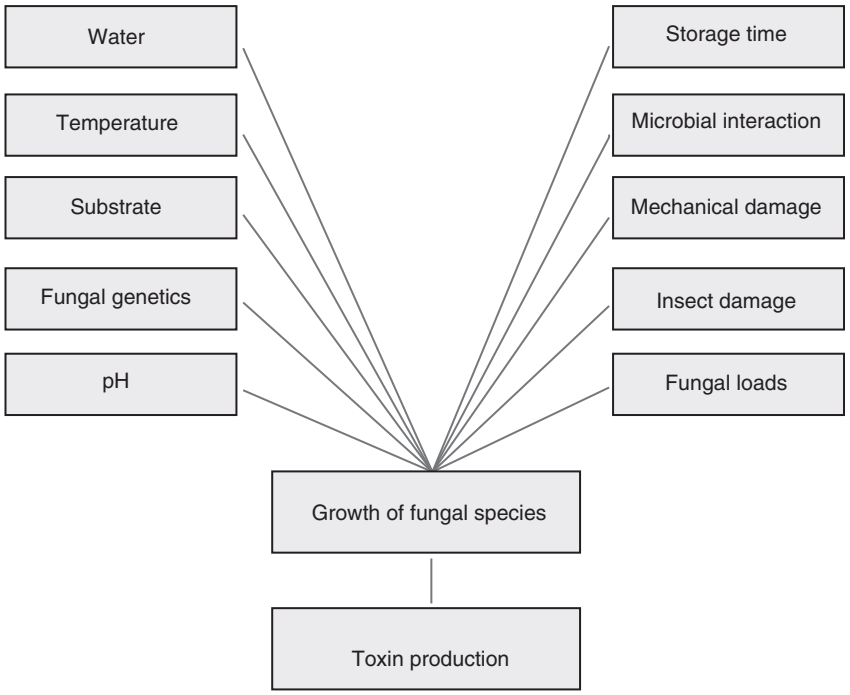

Figure 3 Factors affecting fungal growth and production of mycotoxins.

Table 2 Temperature and minimal water activity (a_w) on fungal growth and mycotoxin production by mean toxigenic fungi

Fungi	*Temperature (°C)*		*Minimum Aw for*		*Toxin*
	Range	*Optimum*	*Growth*	*Toxin production*

[a]Optimum for toxin production.
Abbreviations: DON, deoxynivalenol; DAS, diacetoxyscirpenol.

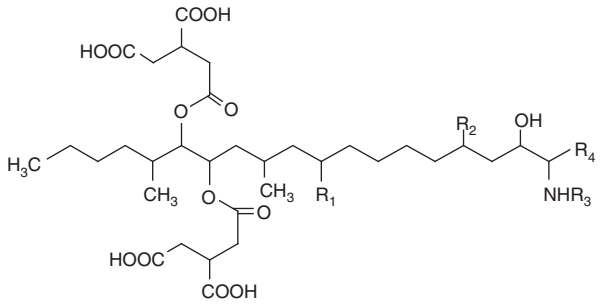
Aflatoxins are characterized by their high toxicity. All domestic and laboratory species are sensitive to the acute toxic, mutagenic, or carcinogenic effects of these compounds, whose target organ is the liver. Aflatoxins are also a great public health concern, as they are involved in the etiology of liver cancer in humans following the ingestion of contaminated foodstuffs.

The genus *Aspergillus* and their toxins are distributed worldwide in foodstuffs and animal feed, but may predominantly be found in tropical and subtropical climates. Plants get contaminated by means of contact with fungal spores in the environment, mainly in the soil, during harvesting and drying. The use of inadequate agricultural practices that increase contact of the products with soil, as well as insect damage to the surface of grains, and inadequate storage in humid and unventilated conditions are pointed out as the main causes that favor contamination and growth of toxigenic fungi.

It is important to emphasize that aflatoxin concentration tends to increase throughout the chain of production and commercialization of animal feed. Jones *et al.* (1982) analyzed raw material and feed production, and the same feed stored in the poultry facilities. They observed that mean contamination was equal to 1.2, 6.0, and 8.8 $\mu g\,kg^{-1}$ aflatoxin, respectively. The same study showed a strong correlation between the period of storage in the poultry facility and aflatoxin frequency

and concentration in the feed. These authors reported that optimal conditions for aflatoxin production in stored feed were 70–89% relative humidity, and temperatures between 19 and 27 °C.

Ochtatoxin A



OT belongs to a large family of mycotoxins that encompasses more than 20 different metabolites among which ochratoxin A (OTA) is the most naturally occurring and the most toxic one. OTs are produced by *Aspergillus* species, mainly by *A. ochraceus* and *A. westerdijkiae*, which are usually found on coffee, cocoa, spices, and dried fruits in tropical regions of the globe. Many *Penicillium* species also produce OTs, such as *Penicillium verrucosum*, which develops on cereals during storage in temperate regions of the world, and *P. nordicum*, which is found on cheese and fermented meat. One of the main features of OTs is that they are not degraded during most food-processing steps, such as fermentation and cooking, and they are thus frequently encountered in food and feed. Cereals, wine, beer, and pork meat are, in this order of importance, the main sources of human exposure to OTs. In addition, another important feature of OTs is that they readily bind to proteins and therefore have also been detected in milk.

OTs are composed of a pentaketide dihydroisocoumarin moiety linked to the amino acid phenylalanine by an amide bond at C7. There is a chlorine atom on one of the hydroisocoumarin rings that strongly contributes to toxicity. Ochratoxin B, which is the dechlorinated form of OTA, is at least 10 times less toxic than OTA.

Fumonisins

Fumonisins constitute a large family of mycotoxins mainly produced by *F. verticillioides*, *Fusarium proliferatum* and other *Fusarium* species. These fungi species are important pathogens of corn responsible for '*Fusarium* kernel rot' or 'pink ear rot.' Fumonisins have also been isolated from cultures of *Alternaria alternata* and *Aspergillus niger* and mainly contaminate grapes. Contamination can occur at different stages, such as crop growth, harvesting, or storage, depending on temperature and humidity. However, development of *Fusarium* species mainly occurs before harvest or in the early periods of storage, when humidity levels are still high ($a_w > 0.9$). Human exposure to fumonisins is of greater importance in countries of South America, Asia, and Africa due to weather and storage conditions, and to higher consumption of maize-based products, as well.

The fumonisin family encompasses 28 structurally related metabolites that can be classified in four series: A, B, C, and P. All of them share a long carbon chain backbone with an amine, but have different hydroxyl, methyl, and tricarboxylic acid side chains (Figure 4). The A series has an acetylated terminal amine group in C2 position, whereas B and C series have free amino groups, and P series have a 3-hydroxypiridinium moiety at this position. C series differ from the rest in that their acyl chain is condensed with glycine instead of an alanine residue, and these compounds have a C19 backbone chain instead of C20. One particular feature of

	R_1	R_2	R_3	R_4
A_1	OH	OH	CH_2CO	CH_3
A_2	H	OH	CH_2CO	CH_3
B_1	OH	OH	H	CH_3
B_2	H	OH	H	CH_3
B_3	OH	H	H	CH_3
B_4	H	H	H	CH_3
C_1	OH	OH	H	H
C_3	OH	H	H	H
C_4	H	H	H	H

Figure 4 Chemical structures of fumonisins.

fumonisin structure is the presence of two tricarbollylic esters on C14 and C15, which are rare in natural products. Type B fumonisins are the most abundant in naturally contaminated commodities. Esterification of the backbone structure produces FB_4, and further oxidation produces FB_2, FB_3, and FB_1. Among type B fumonisins, fumonisin B_1 (FB_1) represents 70% of total fumonisin content, and FB_2 generally accounts for up to 25%. Concerning the other series, only C fumonisins have been detected in corn samples, but at much lower concentrations.

Zearalenone

These are a group of mycotoxins produced by several *Fusarium* species, such as *Fusarium graminearum*, *Fusarium culmorum*, *Fusarium crookwellense*, *Fusarium equiseti*, *Fusarium cerealis*, and *Fusarium semitectum*. In fact, they are produced by most of the toxigenic *Fusarium* species and therefore they are usually detected in combination with other fusariotoxines, such as trichothecenes and fumonisins. As they are produced by *Fusarium* species, zearalenones are mostly encountered in temperate and warm countries on cereal crops, especially on corn, as well as on wheat, oats, and soybean. Production of these mycotoxins mainly takes place in the field, but may also occur during improper cereal storage. Human exposure to zearalenones is essentially caused by consumption of contaminated raw maize and, to a lesser extent, of corn- and wheat-derived products, and beer. The main concern related to exposure to zearalenones is due to the fact that they are one of the most potent families of nonsteroidal naturally occurring estrogens. Zearalenones have a resorcinol moiety fused to a 14-member macrocyclic lactone. There are six major members of this family: zearalenone, α-zearalenol, β-zearalenol, α-zearalanol, β-zearalanol, and zearalanone (Figure 5).

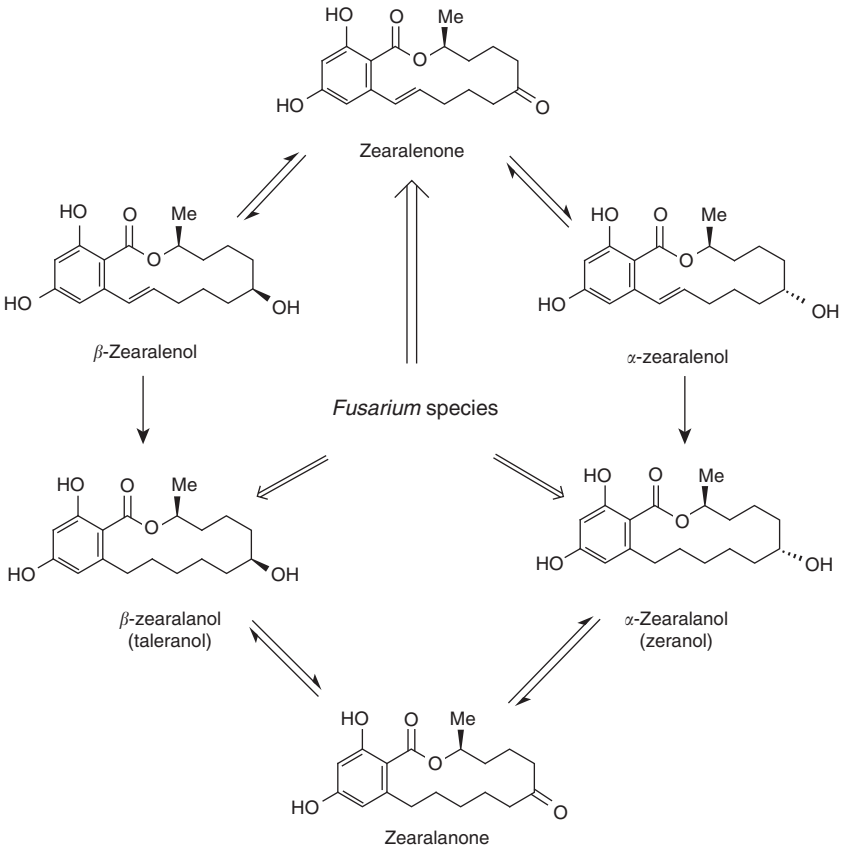


Figure 5 Chemical structures of major members of the zearalenone group.

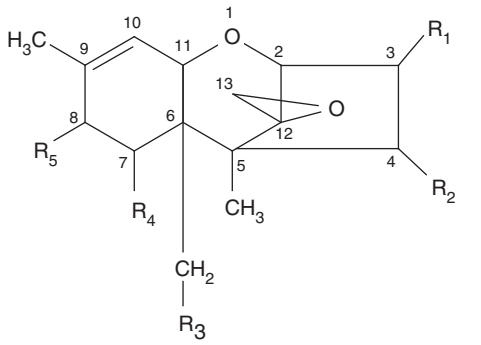
Trichothecenes

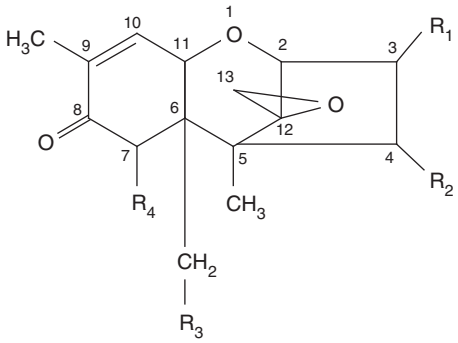
Trichothecenes represent a large family of over 150 secondary metabolites produced worldwide by fungi of different and taxonomically unrelated genera. *Fusarium* species are the most commonly occurring of trichothecene-producing fungi. These species are important plant pathogens that particularly contaminate cereals such as wheat, barley, oats, and maize. They are also responsible for *Fusarium* Head Blight disease, which causes important crop losses worldwide. All trichothecenes are sesquiterpenes, which share a common structural backbone made of a tricyclic nucleus, called trichothecene and, usually, a double bond at C-9,10, and an epoxide at C-12,13 (**Figure 6**). The latter is considered to be very important for toxicity. Based on differences in the position and number of hydroxylations, and the number and complexity of esterifications as well, trichothecenes can be classified in four groups: type A, B, C, and D. Types A and B are the most commonly occurring, and they are generally produced by *Fusarium* species, with *Fusarium sporotrichoides* and *Fusarium poae* producing type A trichothecenes, whereas *F. graminearum* and *F. culmorum* produce type B trichothecenes.



Type A trichothecenes lack a ketide group at C-8 position. The most representative mycotoxins of Type A trichothecene group are T-2 toxin, its hydrolyzed derivate, HT-2, and diacetoxyscirpenol. Type B trichothecenes have a ketide group at C-8 position. Deoxynivalenol (DON), nivalenol (NIV) and their acetylated derivatives (3-acetyldeoxynivalenol, 15-acetyldeoxynivalenol, and fusarenone X, respectively) are the most commonly occurring and the best-characterized mycotoxins of this group.

Occurrence of Mycotoxins in Feedstuffs

Contamination of feedstuffs by toxigenic fungi and their mycotoxins is a worldwide concern, as observed in **Figure 7**. The Food and Agriculture Organization of the United Nations estimated that more than 25% of the worldwide food production is contaminated by some kind of mycotoxin (Benitéz, 2002).



Toxigenic fungi inhabit the most various substrates such as soil, water, vegetables, humans, and animals. From their natural habitat, fungi spread in nature through means like air (the most important mean), water, insects, mites, humans, and animals. They are able to contaminate foods during various production and processing phases, from harvest to transport and storage, especially under favorable conditions of humidity and temperature.

In general, cereals produced in hot and humid regions, where disabled and inappropriate farming techniques and storage conditions, make feedstuffs more susceptible to fungal growth and mycotoxin production. Geographically, within the genus *Aspergillus*, *A. flavus* and *A. parasiticus* species are often

Figure 7 Global distribution of main mycotoxins.

isolated in tropical and subtropical regions, are infrequent in temperate regions, and are rarely isolated in cold climates. *Aspergillus ochraceus* and *P. verrucosum* species are frequent in tropical and temperate regions, respectively. In turn, species of the genus *Fusarium* are distinguished by adapting to different environmental conditions. Thus, *F. verticillioides* species (formerly *F. moniliforme*) predominates in humid tropical and temperate regions, but is infrequent in cold-temperate zones;

F. graminearum, in tropical to temperate regions; *F. poae*, in cold-temperate climate, and *Fusarium sporotrichioides* in cold climates.

Table 3 shows the results of some studies on aflatoxin, fumonisin, and ochratoxin levels in feedstuffs and animal feed in countries worldwide. These results indicate that a large percentage of samples show mycotoxin concentrations that may potentially affect animal productivity. Besides, mycotoxins residues may accumulate in animal tissues or be shed in milk or eggs of animals that ingested feed containing mycotoxins. Foods of animal origin contaminated with residues are additional sources of exposure to humans who ingest these products.

Corn is the main cereal used in animal feed that is susceptible to contamination by toxigenic fungi, although other products may also show fungi and mycotoxins, such as sorghum, cotton meal, and soybean meal, as well as prepared feed. It is important to emphasize that the production of mycotoxins is directly related to the growth of the fungi, whereas the presence of the fungi does not necessarily indicate that the mycotoxin is present, because many toxins are thermostable and are not destroyed in feed grinding and pelletizing processes.

Considering the risks posed by mycotoxins to animal-raising activities, several countries have determined tolerance limits for these toxins in ingredients and animal feed, as shown in Table 4.

Toxicological Effects of Mycotoxins

Aflatoxin

After oral ingestion, mycotoxins may be absorbed at different proportions, with some of them being biotransformed before

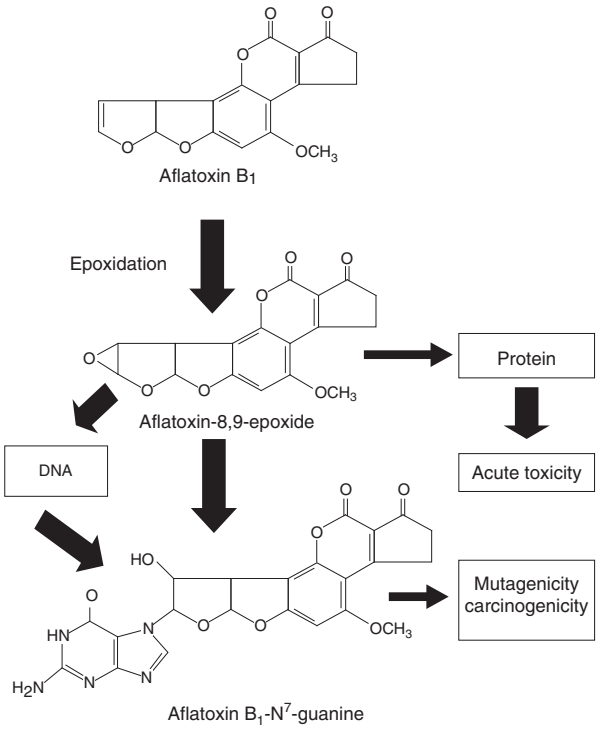

Figure 8 Formation of AFB_1-8,9-epoxide, AFB_1-N_7-guanine and AFB_1-lysine adducts.

urinary or fecal excretion. Aflatoxins are the most studied mycotoxins regarding biotransformation patterns and the biochemical basis of their toxic effects in animal models and in humans. Absorbed AFB_1 and its metabolites are excreted in urine and feces. AFB_1 is concentrated in the liver and, in lesser amounts, in the kidneys. Enzymes of the cytochrome P450 (CYP) family, CYP1A2, CYP3A4, and CYP2A6, are responsible for the biotransformation of absorbed aflatoxins. These enzymes convert AFB_1 into its carcinogenic form, AFB-8,9-epoxide, which bonds covalently to DNA and serum albumin, producing AFB_1-N_7-guanine and lysine adducts, respectively, as shown in Figure 8.

Besides being epoxided, AFB_1 can be also oxidized into several other derivatives. The main hydroxylated metabolites are AFM_1, aflatoxin Q_1 (AFQ_1), a demethylated metabolite, aflatoxin P_1 (AFP_1), and a reduced metabolite, aflatoxicol (Figure 9).

Aflatoxins affect all animal species, although sensitivity to toxic effects is considerably variable among species such as turkeys, quails, ducks, geese, as well as larger domestic animals including cattle, lambs, and pigs. In humans, the most important effect of aflatoxins is the hepatocellular carcinoma. This disease represents more than 80% of primary malignant tumors of the liver, and it is the 7th to 9th most common type of cancer affecting men and women worldwide, respectively.

The particular sensitivity of birds to aflatoxins is related to the quick absorption by their gastrointestinal system. After being absorbed, AFB_1 immediately binds to albumin and spreads to the tissues, mainly the liver, where it is biotransformed by the liver microsomal system. Biotransformed derivatives may bind to intracellular constituents, such as DNA and RNA, and alter protein synthesis functions. In terms of commercial poultry, ducks are the most susceptible species, followed by turkeys, geese, pheasants, and chickens. Dose-response may be different in individuals of the same species, and may vary according to breed, sex, age, and feed composition, among other factors. In many species, males are more susceptible than females, and in general, young animals are more susceptible than adult ones.

Toxic effects of aflatoxins depend on the dose and period of exposure and these factors will determine the occurrence of acute or chronic intoxications. Acute toxic syndrome is related to the ingestion of feedstuffs with high concentrations of aflatoxins, and the following effects may be observed shortly after ingestion: quick deterioration of general condition, loss of appetite, acute hepatitis (Figure 10), jaundice, hemorrhage, and death. The most evident clinical sign of chronic aflatoxicosis is a decrease in the growth rate of young animals due to prolonged, continuous, or intermittent ingestion of feed contaminated with low levels of aflatoxins. Although this is the main form of intoxication in natural conditions, diagnosis is difficult and economic losses may be considerable. Aflatoxicosis in monogastric animals like broilers and pigs is a highly relevant problem because of the economic impact related to mortality, low feed conversion, increased production costs, and negative effects on public health related to human consumption of aflatoxin residues in the viscera of exposed animals.

AFB_1 negatively affects chicken (*Gallus domesticus*) growth, and the effect is more severe during the development of young animals. Serum proteins, succinate dehydrogenase, and glutamate dehydrogenase are sensitive early indicators of this more severe intoxication. Decrease in serum albumin may be used as an early and suitable indicator of the deleterious effects of this mycotoxin in developing chickens. Broilers fed for 35 days with diets containing different levels of AFB_1, had reduced weight gain and histological changes in the liver of birds that received more than 500 $\mu g\ kg^{-1}$ aflatoxin per day. Turkeys submitted to the same treatment showed low weight gain and

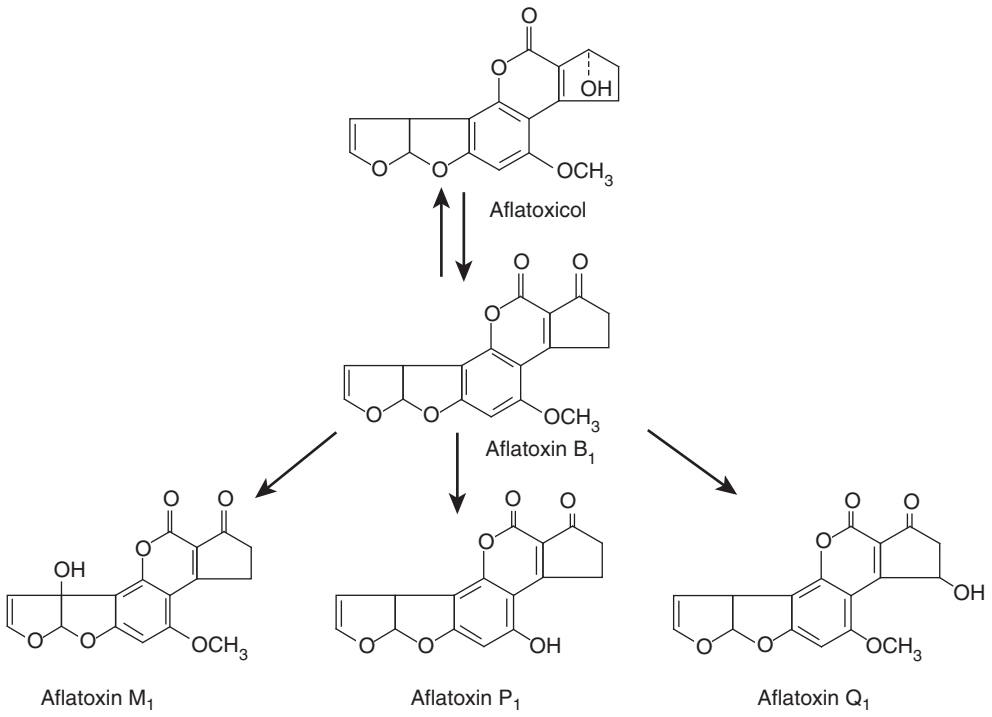

Figure 9 Main metabolites of AFB_1.

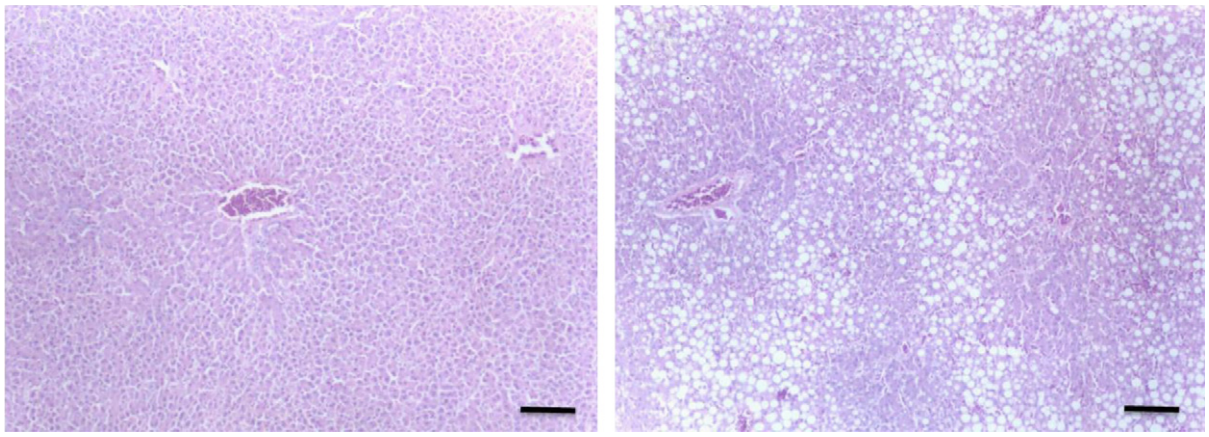

Figure 10 (a) Abdominal overview of a broiler chicken fed 1000 μg kg^{-1} of AFB_1, showing intense liver discoloration. (b) Normal liver of a nonintoxicated broiler.

feed conversion, as well as increased morbidity by different causes, and higher mortality rates, indicating that levels up to 66 μg kg^{-1} AFB_1 in feed were safe for broilers and turkeys.

Jones *et al.* (1982) analyzed five broiler production companies, and selected six growers from each of them. Growers were divided into three categories (good, mediocre, and poor) according to a productivity indicator (mean market weight X 100 per feed conversion). At the end of the study, the authors observed that frequency of feed contamination in good growers was 18% (mean concentration of 6.13 μg kg^{-1}), whereas those classified as mediocre or poor showed contamination frequencies of 22.1 and 31.3% (mean concentrations of 6.5 and 14.0 μg kg^{-1}), respectively. Results demonstrated a significant correlation between mortality rates and carcass condemnation in the groups.

In laying hens, the main symptoms of aflatoxicosis in experimental conditions included reduced egg production and weight; increased hepatic fat, and changes in serum enzyme levels. Ovary atresia in laying hens fed a diet with 8000 μg kg^{-1} AFB_1 for 7 days were also reported. Laying hens fed with 5000 μg kg^{-1} AFB_1 had significant decrease in egg weight, which can be explained by the fact that aflatoxin is primarily metabolized by the liver, the main organ responsible for synthesis and transportation of precursors required for yolk

(a) (b)

Figure 11 Photomicrographs of quail's livers showing (a) normal architecture of parenchyma and (b) intense vacuolar degeneration of hepatic cells and trabecular disorder, after dietary exposure to 100 μg kg^{-1} of AFB_1. Haematoxylin and eosin, bar=60 μm.

production. Toxic effects of aflatoxin in laying hens also include a dose-dependent decrease in egg production and egg quality with increased susceptibility to salmonellosis, candidiasis, and coccidiosis. AFB_1 can have either direct or indirect effects, or both, on the functionality of the gastrointestinal tract of laying hens fed diets containing 0.6, 1.2, or 2.5 mg kg^{-1} AFB_1 for 2 weeks (Applegate *et al.*, 2009).

Aflatoxins are also able to affect the immune system. Immunosuppressing effects demonstrated in domestic birds and other laboratory animals involve aplasia of thymus and bursa of *Fabricius*, reduction in the number and activity of T cells, decrease in antibody response, suppression of phagocytic activity, and reduction in humoral components, such as complement (C4), interferon, and immunoglobulins IgG and IgA. All these changes associated with the exposure of animals to feed contaminated with aflatoxins contribute to the occurrence of concomitant infections caused by viral and bacterial agents.

Concentrations of approximately 300 μg kg^{-1} AFB_1 in the feed of monogastric animals may lead to immunosuppression without any apparent clinical effects. Also, the ingestion of the toxin may be responsible for morbidity or mortality in the flock due to secondary infections. Signs observed in the animals often included significant decrease in T cells, albumins, and globulins.

Aflatoxins poisoning in turkeys cause inappetence, reduced spontaneous activity, unsteady gait, recumbence, anemia, and death. In the postmortem examination, body condition was adequate most of the times, but generalized congestion and edema were observed. Liver and kidneys were congested, enlarged, and firm. Aflatoxins in doses equal or greater than 200 μg kg^{-1} affected turkey performance during a period of 1–42 days. The effect of those toxins on body weight, feed consumption, relative weight of gizzard and liver, mortality, and total protein and cholesterol levels in serum was dependent on the dose. Turkey poults were very sensitive to aflatoxin poisoning, and inadequate mycotoxicological management may cause important economic losses in turkey production.

Chronic exposure of Japanese quails to diets containing AFB_1 adversely affected their performance, especially feed intake, egg weight, and percent eggshell. Intense vacuolar degeneration of hepatic cells and trabecular disorder were also seen after dietary exposure to 100 μg AFB_1 kg^{-1} (Figure 11). Addition of 2.5 and 5 mg kg^{-1} aflatoxin to quail diets led to significant changes in pancreatic alpha and beta cells, and these changes may have a negative effect on carbohydrate metabolism of poultry.

The simultaneous occurrence of aflatoxins and other mycotoxins in feedstuffs has become a greater concern to the animal production, especially in poultry, because of the possibility of interaction effects. The effects of prolonged oral administration of AFB_1 and fumonisin B_1 were evaluated in broilers from 21 to 42 days of age, indicating that either FB_1 or AFB_1, alone or in combination, did not cause marked changes in hematological and serological parameters of broilers, but caused important lesions in liver and kidneys (Del Bianchi *et al.*, 2005).

In swine, clinical signs of acute aflatoxicosis may begin after 6 h of ingestion, leading to severe depression, inappetence, bloody stools, muscle tremors, and motor incoordination with hyperthermia (up to 41 °C). Death may ensue in the following 12–24 h. In subacute intoxication, clinical signs evolve more slowly, and the following symptoms are observed: erect bristles, hyporexia, lethargy, and depression. In parallel, animals may show jaundice, dehydration, and emaciation, with reddish areas on the skin, and progressive weight loss. Chronic intoxication is manifested by decreased weight gain and feed conversion, inappetence, poor general appearance and, sometimes, diarrhea.

In dogs, early signs of aflatoxicosis include depression, loss of appetite, and vomiting. Later stages include orange-colored urine and jaundice. Severely affected dogs produce blood-tinged or blackened stools with difficult vomiting and internal bleeding. Outbreaks of aflatoxicosis in dogs have been reported in several countries, especially in the United States, usually associated with consumption of contaminated feed containing >200 μg kg^{-1} feed.

As the disease advances to the final stages in all animal species, signs of ataxia are frequently seen, besides jaundice and, sometimes, seizures. When high levels of the toxin are ingested, the liver shows fatty degeneration, lobular necrosis with increased number of basophilic cells in the periphery of

the lobule, proliferation of biliary ducts, and cirrhosis. A jaundiced carcass associated with an edematous and yellowish liver, are strong indicators of intoxication. The gall bladder may be edematous, and the liver, friable and hyperemic, mainly in cases of acute intoxication. Blood clotting times are also decreased, and collections of bloody liquid may be observed in the cavities and in mucous membranes, as well as hemorrhage in muscle masses.

Ochratoxin A

Although OT were first isolated from the species *A. ochraceus* (previously known as *Aspergillus alutaceus*), these toxins may be produced by several species in the genera *Aspergillus* and *Penicillium*. The ochratoxin group has 7 components, but only OTA has been found worldwide as a natural contaminant of grains. The kidneys are the target organs of OTA, which interferes in the synthesis of macromolecules in cells of the renal parenchyma, including DNA, RNA, and proteins. Besides, it affects renal carbohydrate metabolism, damaging the epithelium of the proximal tubules (Figure 12) and causing osmotic diuresis by means of decreased absorption of electrolytes and increased excretion of water.

OTA causes a series of adverse effects in most domestic animals. In pigs, it is the causative agent of mycotoxic porcine nephropathy. Similarly, in humans, it is recognized as the etiological agent of the Balkan endemic nephropathy. In poultry, OTA is considered to be the most potent mycotoxin, showing high lethality rates. LD_{50} for broilers is approximately 2.1 mg kg^{-1} of body weight, whereas LD_{50} for AFB_1 is 6.8 mg kg^{-1}. Ochratoxicosis in swine is observed as decreased weight gain, as well as polydipsia, polyuria, and renal lesions. Doses of 200 μg kg^{-1} of OTA in the feed were enough for the animals to present nephropathy, leading to negative impact in feed conversion and weight gain. Mortality may reach 90% in affected lots.

Natural occurrence of outbreaks in turkey breeding facilities due to the presence of OTA in animal feed showed levels ranging from 0.2 to 16.0 mg kg^{-1}, with a mortality rate of 59%, and decrease in feed consumption of 20%. Outbreaks involving laying hens were characterized by decreased egg production, low quality of eggshell, and nephropathy. In broilers, these authors observed low growth rate and feed efficiency, little pigmentation of the carcasses, and nephropathy. In experimental trials, broilers given more than 2.0 mg kg^{-1} OTA in their feed showed decreased weight gain, relative increase in kidney and liver weight, decreased serum levels of total proteins, albumins, globulins, and cholesterol, and increased creatinine and uric acid concentrations.

In broilers fed diets containing 2.0 mg kg^{-1} OTA, a significant reduction in the breaking strength of large intestines was observed, along with increased relative weight of the organ. This finding is important when considering the possible rupture of intestines during poultry processing, which would lead to fecal contamination of the carcass. Male broilers fed diets containing 400 and 800 μg kg^{-1} OTA showed significant decrease in body and thymus weight, feed consumption, feed conversion ratio, and thyroxin concentration. OTA-treated groups developed anemia manifested by a significant decrease in red cell counts (37%), packed cell volume percentage, and hemoglobin concentration. White cell counts, humoral immune response, and cell-mediated immunity were also significantly reduced. The greatest concentrations of OTA (2 and 4 mg kg^{-1}) ever given to broilers produced significant depression in growth rate, reduced feed consumption, and poor feed conversion efficiency and immune response (Verma *et al.*, 2004).

Fumonisins

Fumonisins comprise the latest group of mycotoxins discovered. Since their isolation in 1988, these toxins have been associated with previously known animal diseases, such as

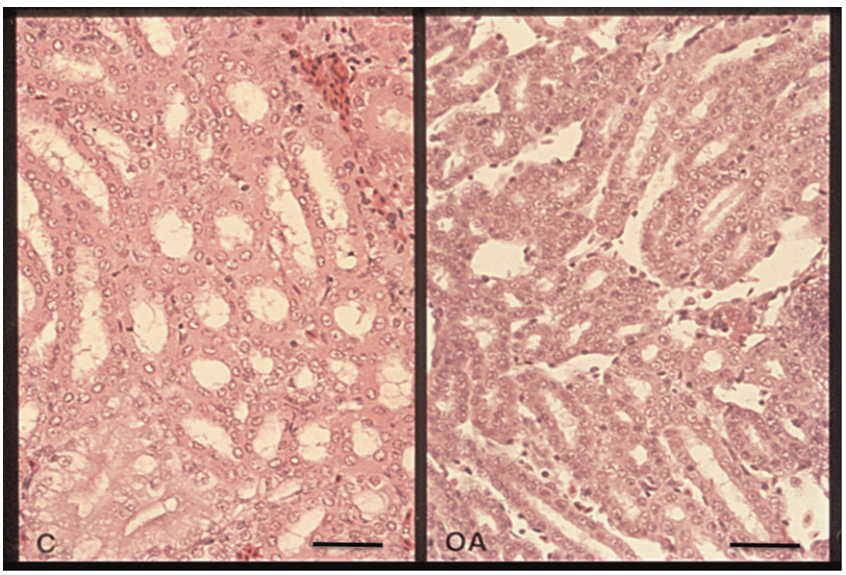

Figure 12 Photomicrographs of broiler's kidneys showing normal architecture of tubular (C) and tubular ephithelium hyperplasia after intoxication with ochratoxin A (OA). Haematoxylin and eosin, bar = 180 μm (Courtesy of Dr. David Ledoux, University of Missouri, USA).

equine leukoencephalomalacia and porcine pulmonary edema. Studies with rodent hepatocytes have shown that fumonisins block sphingolipid production (Figure 13). This evidence corroborates the hypothesis that the interruption of sphingolipid production and the consequent accumulation of sphinganine and sphingosine are the main toxic mechanisms of fumonisin acute toxicity and carcinogenicity. Sphingolipids are important compounds in the maintenance of cell membrane integrity, as well as in the regulation of cell surface receptors, ion pumps, and other vital systems for cell function and survival.

Swine are very sensitive to fumonisin intoxication. This sensitivity has been observed in several natural and experimental outbreaks. The main target organs of fumonisin in swine are the lungs, liver, heart, and pancreas, and the specific syndrome in pigs is called porcine pulmonary edema. The disease has been experimentally reproduced by supplying grains contaminated with *F. verticillioides*, culture material, and intravenous administration of pure FB_1, besides other effects caused by this mycotoxin in these animals, such as hepatic alterations and increased serum cholesterol (Haschek *et al.*, 2001).

Although fumonisins are highly toxic for horses and pigs. However, *F. verticillioides*-contaminated culture material has been shown to induce toxic responses when fed to chickens, ducklings, and turkey poults. Toxicity signs included increased mortality; reduced size of the bursa of *Fabricius*, thymus, and spleen; decreased body weight gain; myocardial degeneration and hemorrhage; changes in hemostatic mechanisms; and necrosis of hepatocytes. Most of the reports on toxic effects of FB_1 in avian species involve chickens and turkeys. High levels of this toxin fed to these species are associated with reduced body weight and feed intake, diarrhea, poor performance, and alterations in hematological and biochemical parameters, with increased activity of the enzymes alanine transaminase and aspartate transaminase (Asrani *et al.*, 2006).

Broilers fed diets of FB_1 had diarrhea, reduction in weight gain, increase in liver weight, histological changes, such as multifocal hepatic necrosis, biliary hyperplasia, muscle necrosis, and rachitism. Broilers receiving 75 mg kg^{-1} FB_1 showed only reduced sphingolipid biosynthesis, indicating that, although clinical signs may not be evident, concentrations as low as 75 mg kg^{-1} FB_1 may be toxic for birds. Immunosuppression is also pointed out as one of the main toxic effects of FB_1, with reports of decreased humoral immunity and lymphocyte suppression.

Fumonisins significantly increased total serum protein and albumin concentrations on 14 and 21 days postfeeding (DPF), serum calcium and cholesterol levels from 14 DPF onward, and creatinine from 21 DPF onward (Asrani *et al.*, 2006). This study revealed that the addition of *F. verticillioides* culture material supplied 300 mg kg^{-1} FB_1 of diet, a highly toxic concentration to quail chicks, resulting in heavy mortality, decreased growth rate, and significant alterations in hematological and biochemical parameters.

When performance is considered, 50 mg kg^{-1} FB_1 were detrimental to turkeys but not to broilers fed to market age. Liver sphingolipid results indicated that 25 and 50 mg kg^{-1} increased the sphinganine/sphingosine (SA:SO) ratio, but no significant toxic effect was observed. The altered SA:SO ratio with no concurrent disease suggested that this ratio is an extremely sensitive biomarker of exposure to FB_1, but may

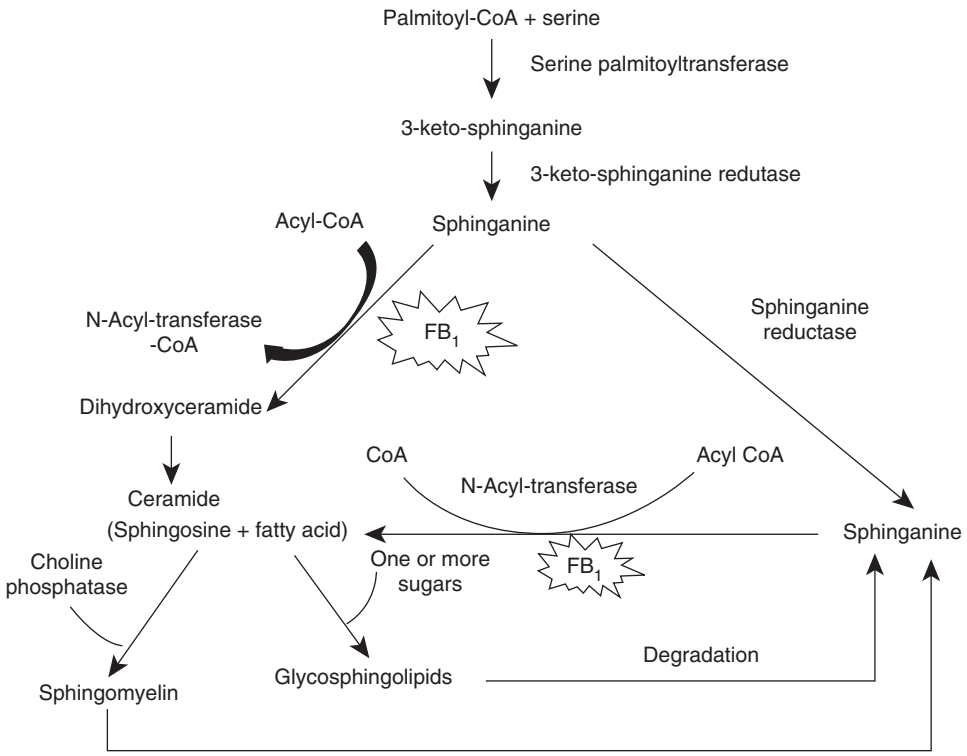

Figure 13 Sphingolipid metabolism disruption by fumonisin B_1.

not be a good indicator of clinically significant disease in poultry.

Interactions between fumonisin and other *Fusarium* toxins in poultry have also been reported. Kubena *et al.* (1999) observed few deleterious effects on the performance and health of adult laying hens given feed containing 100–200 mg kg^{-1} FB_1 and 50–100 μg kg^{-1} moniliformin for a prolonged period of time (420 days). However, Prathapkumar *et al.* (1997) studied natural mycotoxicosis outbreaks in laying poultry, and reported dark and viscous feces, 20% reduction in egg production, and 10% mortality. Flocks showed evident improvement after they stopped receiving the contaminated feed. Analysis of the feed showed contamination levels of 8.5 mg kg^{-1} FB_1 and 100 μg kg^{-1} AFB_1, evidencing the additive effects of the two toxins.

Exposure to FB_1 at concentrations ≥ 50 mg kg^{-1} adversely affected quail performance, causing a reduction in feed intake and lower weight gain. Egg production, weight, and eggshell weight were also affected. Eggshell depigmentation was also observed, and became more marked with increasing concentrations of FB_1 in a dose-dependent relationship (Butkeraitis *et al.*, 2004).

Zearalenone

Zearalenone was first detected after hyperestrogenism symptoms appeared in swine fed moldy maize. These include prolonged estrus, anestrus, changes in libido, infertility, increased incidence of pseudo pregnancy, increased udder or mammary gland development, and abnormal lactation. The toxin is also related to the following secondary complications: stillbirths, abortions, mastitis, vulvovaginitis, and rectal or vaginal prolapses (Figure 14).

Endocrine disruption related to zearalenone is attributed to both genomic and nongenomic effects. First, zearalenone competes effectively with endogenous steroid estrogens, such as 17β-estradiol for the specific binding sites of estrogen receptors, with no preference between the two isomers, estrogen receptor-α, and estrogen receptor-β. Estrogen receptors are found in many different organs, such as the uterus, the mammary glands, the bones, the liver, and the brain, where zearalenone can, therefore, have an impact. Relative binding affinities of the main metabolites are as follows: α-zearalanol > α-zeralenol > β-zearalanol > zearalenone > β-zearalenol. The α-isomers are approximately 10-fold more active than the rest because of the position of the hydroxyl group. Differences in production of α or β isomers explain differences in sensitivity between species. For instance, pigs produce more α-ZEL, whereas poultry species produce more β-zearalenol.

The estrogenic potency of zearalenone shows species-specific differences, and pigs, especially gilts, are considered to be the most susceptible animal species, whereas poultry and ruminants show a higher tolerance to zearalenone-contaminated feeds. Mechanistic studies showed that zearalenone interacts not only with estrogen receptors, but also influences the activity of enzymes involved in the steroidogenesis in the liver and in the reproductive organs. *In vivo* and *ex vivo* experiments show that zearalenone and its metabolites impair oocyte maturation and embryonic development, but do not cause

Figure 14 Hyperestrogenism in a swine female showing vulvovaginitis and vaginal prolapse (Courtesy of Dr. David Ledoux, University of Missouri, USA).

major teratogenic effects. *In vitro* experiments indicated that zearalenone is nonmutagenic, and long-term studies in rodents provided inconclusive evidence for carcinogenicity.

Various studies have addressed the effects of zearalenone in pigs. The source of zearalenone that have been used is either crystalline zearalenone, or highly contaminated zearalenone-containing feedingstuffs. Initial studies suggested that an effective dietary zearalenone concentration producing clear estrogenic effects would be higher than 1 mg kg^{-1} feed. In more recent studies using crystalline zearalenone, estrogenic effects have been reported at concentrations ranging from 0.05 to 0.4 mg zearalenone kg^{-1}. In a study conducted with nonpregnant gilts exposed to 0, 0.04, 0.2, and 0.4 mg kg $b.w.^{-1}$ during days 5–20 of estrus, a no-effect level of 0.04 mg kg b.w. day^{-1} was observed. Several studies have indicated that the female prepubertal pig is particularly sensitive to the estrogenic effects of zearalenone. Using naturally contaminated maize providing dietary concentrations of zearalenone from 0.01 to 0.42 mg kg^{-1} and of DON from 0.2 to 3.9 mg kg^{-1} feed clear estrogenic effect (increased swelling of cervix and increased mean relative uterus weight) was observed at the highest dose level of 0.42 mg kg^{-1} zearalenone in feed. A slight decrease in mean serum follicle-stimulating hormone concentration in the dosed groups was considered influenced by the cooccurrence of DON in the feed. Although only a few studies have been conducted, boars seem to be quite resistant to the effects of zearalenone (EFSA, 2004).

Zearalenone, has also been administrated either orally or intramuscularly, at doses of 50, 200, 400, and 800 mg kg b.w.

day^{-1} for 7 days to broilers. A dose–response related increase of the oviduct weights was found but the potency of zearalenone was estimated to be only 1.37% of that of oestradiol propionate. In turkeys, the oviducts and testes were unaffected at dietary zearalenone concentrations of 10, 25, 50, 100, 200, 400, and 800 mg kg^{-1} diet (week 4–7 of age). Dewlaps and combs showed an increased development and a considerable strutting behavior were observed at 400 and 800 mg kg^{-1} diet. A hyperandrogenic response was observed in male turkeys fed a diet with 800 mg crystalline zearalenone kg^{-1}. Cystic alterations of the lamina epithelialis of the oviduct of female Leghorn chicks, hyperactivity of secreting cells of the oviduct, and atrophy of testes was reported in male chicks exposed to 10 mg kg b.w. day^{-1} for 20 days. The reduced testes weights and the increased weight of the oviducts of ducks to the presence of 0.15 mg kg^{-1}. However, other mycotoxins were also present in the diet in this case (EFSA, 2004). From these experiments poultry can be regarded as quite tolerant to zearalenone as symptoms of hormonal effects were only observed at high zearalenone doses, which will hardly occur under practical feeding conditions.

Deoxynivalenol

DON is also known as vomitoxin due to its emetic effects after acute exposure. In addition to that, symptoms caused by acute exposure are similar to those observed after ionization: abdominal pain, salivation, diarrhea, vomiting, leukocytosis, and gastrointestinal hemorrhage. Chronic exposure to DON causes feed refusal due to alterations of serotogenic activity of both the peripheral and central nervous system. Other effects related to chronic ingestion of DON are weight loss, growth retardation, intestinal irritation, disruption of immune response, and death. Toxicity of DON is caused by the same molecular mechanisms of the other trichothecenes. Immune modulation induced by DON has been extensively studied, and it has been shown that inflammation arises from mitogen-activated kinase activation, followed by activation of the prostaglandin-endoperoxide synthase 2, and a consecutive increase of prostaglandins, which triggers the production of inflammatory cytokines.

Swine and other monogastric animals show the greatest sensitivity to trichotecenes, followed by birds. NIV and DON induce feed refusal and weight loss, show similar toxicities and a combined concentration lower than 0.4 mg kg^{-1} is described as acceptable for swine, which is a relatively susceptible species.

Recently, DON has been shown to maintain inflammation by favoring the Th-17-related immune response, which could be associated with chronic inflammatory intestinal diseases (Cano *et al.*, 2013). The intestine is, in fact, one of the most sensitive organs to DON exposure. Low doses of this toxin can induce morphological and histological impairment of intestinal epithelial cells, and alter intestinal permeability (Pinton *et al.*, 2012). DON toxicity has, thus, repercussions on the neuroendocrine system, the intestinal system, and the immune system. The immune system appears to be the most sensitive to DON concentrations, followed by the neuroendocrine system, and finally, by the intestinal system. Among farm species, swine show the greatest sensitivity to trichotecenes, followed by poultry and ruminants.

Many feeding studies have been done on pigs using either crystalline DON or naturally or artificially infected cereals mixed. The effects of pure DON added to feed and naturally contaminated feed containing similar levels of DON have been compared in at least four feeding studies with pigs. Naturally infected feed had a stronger effect on the feed intake and weight gain than pure toxin in all these studies comparing the difference sources of DON. The difference remains to be explained, but proposed hypotheses include the presence of other toxins in the material, the presence of other compounds (as for example bacterial polysaccharides) or the matrix effect. Complete feed refusal was observed at levels of 12 mg kg^{-1} of crystalline DON and vomiting at 20 mg kg^{-1} feed. The consumption of DON-contaminated feed has been associated also with epithelial lesions in the esophageal region of the stomach when pigs have been given naturally infected feed containing from approximately 3–6 mg DON kg^{-1} feed. The negative effect on feed intake in pigs is generally considered as most sensitive endpoint of toxicity.

Changes in different clinical chemistry parameters (plasma nutrients and plasma enzyme activities) have been reported from several studies whereas in other experiments no changes were observed. Reported alterations are probably due to the reduced feed intake and not a direct effect of the toxin since no changes in these parameters were observed when compared to pair-fed controls.

Effect of DON on the pig immune response has also been investigated. In many experiments, DON increases IgA concentrations in blood serum, generally when DON levels exceed 1 mg kg^{-1} feed (Accensi *et al.*, 2006; Pinton *et al.*, 2008).

Prevention of Mycotoxicoses

Every effort must be made to reduce the occurrence of mycotoxins. This is a complex task that requires an integrated understanding of crop biology, agronomy, fungal ecology, harvesting methods, storage conditions, food and feed processing and technology, and detoxification strategies. There are a number of approaches that can be followed to minimize mycotoxin contamination in the food and feed chains. They involve prevention of fungal growth and therefore mycotoxin formation, as well as strategies to reduce or eliminate mycotoxins from contaminated food commodities.

Preventative Measures to Avoid Grain Contamination

The methods for controlling fungal growth in foods include: physical control, by drying products in safe levels of humidity (water activity and moisture content), cooling under modified or controlled oxygen and carbon dioxide atmosphere and using irradiation process; chemical control, by using organic acids (propionic, sorbic, acetic, and formic), fumigants (phosphine), and compounds isolated from plant extracts; biological control, by using microorganisms competing for space and nutrients, antibiosis and activation of defenses; and genetic control, by using seeds resistant to toxigenic fungi.

Processing may reduce, but not eliminate mycotoxins in cereals, and they become a potential risk for consumers (Lombaert *et al.*, 2002). Therefore, to avoid the presence of mycotoxins, prevention by using good agricultural practices during harvesting and storage of grains is the best option. Biological control may be an ally when the following strategies are used in the agriculture: pulverization of antagonists during the blooming period, treatment of infected seeds, and inhibition of inoculum production by organisms specialized in degradation (Larsen *et al.*, 2004). Therefore, practices that decrease the presence of insects in grain crops, and humidity during storage of raw material and feeds may work well as prevention strategies.

Procedures applied to decrease the moisture in harvested grains and storage under internationally recommended standards are also essential measures to avoid toxigenic fungi and mycotoxins.

Detoxification Methods

Detoxification methods may be the physical removal of contaminated grains, or removal of the toxin by polar solvents, destruction by heat, or degradation by chemical substances or microorganisms. Although these methods may be effective, they are extremely expensive and therefore not economically viable. Heat is one physical method considered as able to decrease FB_1 concentration in corn grains from 87% to 100%. However, temperature has to be approximately 150–220 °C, leading to a possible loss of nutritional content. Simply washing the grains with water and sodium carbonate solution may reduce fumonisin concentration in corn. Initial cleaning of the corn in mills led to a 40% reduction in the concentration of aflatoxins, and 32% in fumonisins (Scudamore and Patel, 2000). However, these techniques have little applicability for large amounts of grain, as used in animal feed plants.

In the animal industry, one of the most used strategies to reduce the exposure to mycotoxins is to decrease their bioavailability by including various mycotoxin adsorbing agents in the compound feed, which leads to a reduction in mycotoxin uptake, as well as in the distribution to the blood and target organs. A diverse variety of substances have also been investigated as potential mycotoxin-detoxyfying agents. Depending on their mode of action, these feed additives may act by reducing the bioavailability of the mycotoxins or by degrading them or transforming them into less toxic metabolites.

Another strategy is the degradation of mycotoxins into nontoxic metabolites by using biotransformation agents, such as bacteria/fungi or enzymes. Substances that do not directly interact with mycotoxins, i.e., antioxidant agents, immunostimulatory agents, are not considered *sensu stricto* as mycotoxin-detoxifying agents. However, such compounds may be very efficient in the reduction of the toxicity of some mycotoxins.

There is a wide variety of chemical products that may be applied to high-moisture stored hay in order to control microbial growth. Among these products, ammonia may be highlighted. Besides acting in the control of fungi by increasing pH, it also affects the fibrous portion of the forage, solubilizing hemicellulose, and increasing the availability of readily fermentable substrates for rumen microorganisms.

Chemical Adsorbents

The use of adsorbent substances is the most common strategy to prevent the toxic effects of mycotoxins that are already formed in foods. Several minerals have been evaluated, probably because of there are easy to incorporate in feeds, without the need for any special equipment. The main mechanism of adsorption of these materials is related to charges exchanged between the adsorbent substance and the mycotoxin. However, as mycotoxin structures are different, the efficacy of chemical adsorbents is not similar for all of them.

One of the most important characteristic of adsorption is the physical structure of the adsorbent, that is, the total charge and total distribution, the size of the pores, and the accessible surface area. However, the property of the adsorbent molecules, the type of mycotoxin, as well as the polarity, solubility, size, shape and, in the case of ionized compounds, charge distribution and dissociation constants also have an important role. Therefore, the efficacy of the whole adsorption process has to be analyzed in relation to the particular properties of the adsorbent (Huwig *et al.*, 2001). The most used chemical adsorbents are activated charcoal, aluminum silicates, and mannan oligosaccharides (MOS).

Activated charcoal

Activated charcoal is an insoluble, very porous powder with large surface in relation to its mass (500–3500 $m^2\,g^{-1}$), formed by the pyrolysis of organic material. It has been used as an antidote against poisoning since the nineteenth century. Therefore, it may also inactivate mycotoxins. In an aqueous solution, it may adsorb most of the mycotoxins efficiently, considering that different activated charcoals have little or no effect against mycotoxins. This may be due to the fact that activated charcoal is a relatively unspecific adsorbent and, therefore, essential nutrients may also be adsorbed, particularly if their concentration in feed is much greater than that of mycotoxins. In studies with goats, however, it was observed that high doses of activated charcoal were beneficial in acute intoxications caused by the ingestion of large amounts of aflatoxin. The adsorption of chemical substances by vegetable charcoal depends on several factors: size of the pores, surface area, chemical nature of the xenobiotic compound, dose of the vegetable charcoal, pH, and gastrointestinal content.

Aluminum silicates (zeolites, hydrated sodium calcium aluminum silicate, and clay)

Most of the studies related to mycotoxin reduction by the use of adsorbents are based on the use of aluminum silicates, mainly zeolites, hydrated sodium calcium aluminum silicate (HSCAS), and aluminum silicate clay. All of them are aluminates, silicates, or some interchangeable ions of alkali metals, mainly alkali metals and alkaline earth metals. Several studies show that phyllosilicates have the ability to chemically adsorb aflatoxins in aqueous solutions. Some aluminum silicates bind

to AFB_1 *in vitro* at variable degrees, and form complexes of different strengths with AFB_1.

HSCAS form a more stable complex with AFB_1 than many other compounds that were tested *in vitro*. It was discovered that HSCAS, bentonite and montmorillonite clays protect laboratory animals from the toxic and teratogenic effects of aflatoxins. HSCAS is a phyllosilicate whose deficiencies in positive charges create a potential to adsorb positive charges or cationic compounds.

Many studies have demonstrated that the addition of adsorbents may effectively reduce aflatoxin toxicity in animals. Determining the mechanism of adsorption of the aflatoxin may make it easier for more efficient adsorbents to be identified or prepared. Phillips *et al.* (1995) analyzed the aflatoxin adsorption mechanism by HSCAS. They suggested that adsorption may involve the β-dicarbonyl system of aflatoxin by means of the chelation of metallic ions on the surface and HSCAS phyllosilicate layers. Aflatoxin is chemically adsorbed in different sites that may include the interlamellar region, borders, and basal surfaces of HSCAS particles. Binding of aflatoxin by HSCAS is so stable that when HSCAS is in animal feed, traditional extraction procedures (methanol-water) for the analysis of aflatoxins have to be modified, and a nonaqueous solvent is necessary.

Zeolites are crystalline, hydrated alkaline aluminum silicates, and alkaline earth cations with infinite possibilities of tridimensional structure. They are characterized by the high capacity of gaining and losing water in a reversible fashion, and to exchange constituent cations without great changes in their structures.

Studies have been carried out to determine if the use of zeolites in the diet of broilers had any beneficial effect. The inclusion of zeolites in broiler feed increased body weight gain and feed efficiency, which favored the feed conversion in mass, increased specific gravity of eggshells, and increased the use of calcium. The inclusion of 5% zeolite or more in the feed of growing and fattening swine significantly increased feed conversion from 35 to 65 kg of body weight. However, there is some evidence that zeolites may interfere with mineral distribution in the tissue, for example, negatively affecting the use of dietary phosphorus by broilers (Moshtaghian *et al.*, 1991).

Bentonite comes from the disaggregation of volcanic ashes *in situ*, and is mainly made up of montmorillonite. Bentonite composition may vary from one deposit to the other, mainly because of interchangeable ions, Na^+, K^+, Ca^{2+}, and Mg^{2+}. These are referred to as sodium, potassium, calcium, and magnesium bentonite. They have a layered (lamellar) crystalline microstructure that enables the adsorption of other molecules, and have the marked ability to swell when water is added. This adsorbent compound has several uses in the industry, engineering, and agriculture, including clarification of beverages and water, and discoloration of oils. Bentonites have demonstrated the ability to improve growth rates and feed efficiency in broilers, such as the use of energy and protein, and increased feed passage time. Supplement in the diet of laying hens with 2.5–5% bentonite improved laying rates, feed efficiency, size of the egg, quality of the eggshell, and decreased mortality and fecal moisture content. Beneficial effects of bentonites were also reported on nutrient retention in turkeys, and egg production and feed efficiency in hens.

Mannan oligosaccharides

MOS are derived from the cell wall of yeasts (*Saccharomyces cerevisiae*) and have a high degree of antigenicity, mainly due to the mannan and glucan components. MOS may be used as aflatoxin adsorbents because they reduce the problems caused by mycotoxins normally found in low-quality maize. MOS have the ability to bind to different pathogens in the gastrointestinal tract and therefore prevent that they colonize it. *In vitro* studies showed that commercial MOS adsorbed AFB_1 and zearalenone (Devegowda *et al.*, 1998), and the addition of esterified glucomannan in the diet of broilers was effective to neutralize the toxic effects of naturally aflatoxin-contaminated diets.

Microbiological Strategies

Microorganisms with ability to bind with mycotoxins

Biological decontamination methods are being widely studied and may be a very promising choice, provided that they are efficient, specific and environmentally correct. Of all kinds of microorganisms available and that may be used for aflatoxin removal from a contaminated medium, yeast and lactic acid bacteria (LAB) are the most studied and promising ones.

Saccharomyces cerevisiae was originally used in animal feeds as growth promoters; however, these organisms have showed to be also useful against aflatoxin contamination because of the ability of its cell wall to bind to the mycotoxin. The adsorbent effect of *S. cerevisiae* is attributed to the esterified glucomannan, which is extracted from the yeast cell wall. Shetty and Jespersen (2006) showed that most of the yeast strains bound to more than 15% of AFB_1, and the bond with toxin was highly strain-specific.

In the poultry industry, *S. cerevisiae* has been used as a general performance promoter in poultry feed, and showed beneficial effects against the exposure to aflatoxin.

Regarding LAB, El-Nezami *et al.* (1998) found some strains of *Lactobacillus* (*Lactobacillus rhamnosus* GG and *Lactobacillus rhamnosus* LC-705) that were able to bind efficiently with large amounts (up to 80%) of AFB_1 in the medium. Peltonen *et al.* (2001) studied 15 types of *Lactobacillus* and five types of *Bifidobacterium*, and found binding with AFB_1 ranging from 5.6% to 59.7%. A minimum concentration of 2×10^9 CFU ml^{-1} of *Lactobacillus* and *Propionibacterium* is required to bind to 50% of the AFB_1, and binding is greater when LAB concentration reaches 10^{10} CFU ml^{-1}. The binding effect is dependent on the temperature, once the efficiency in aflatoxin removal is greater at 37 °C than at 4 °C and 25 °C. Gram-positive bacteria are best sequesters of aflatoxin from the medium than Gram-negative ones, with removal rates of 80–20%, respectively, suggesting that the ability to remove the toxin is dependent on the structure of the cell wall (Bolognani *et al.*, 1997).

Data available today show that bacterial viability is not a requisite for the removal of the toxin, and that the adsorption process occurs rapidly, once nonviable cells were more efficient, and there was no difference in the intervals analyzed. Therefore, it is necessary to study new bacterial cells, to have greater understanding of the mechanism of action of these

bacteria on aflatoxins in order to identify those that are more efficient in the removal of mycotoxins and therefore help to reduce human and animal exposure to these contaminants.

Microbial degradation of mycotoxins

Aflatoxin biodegradation using microorganisms offers an attractive alternative for the control or elimination of aflatoxins in foods and feeds, protecting their quality and safety. Many species of fungi and bacteria, such as *Flavobacterium aurantiacum*, *Corynebacterium rubrum*, *Candida lipolitica*, *A. niger*, *Trichoderma viride*, *Armillariella tabescens*, *Nurospora* spp., *Rhizopus* spp., *Mucor* spp., among others, have shown the ability to enzymatically degrade mycotoxins. However, there are still unanswered questions about the toxicity of enzymatically degraded products and undesirable effects of the fermentation of nonnative microorganisms in the quality of the feed (Shetty and Jespersen, 2006). Microorganisms predominant in fermented cereals are lactic acid bacteria and yeasts, specially *S. cerevisiae* and *Candida krusei* (Jespersen, 2003).

Enzymatic or microbial degradation of mycotoxins ('biotransformation') leading to less- or even nontoxic metabolites is a strategy for the decontamination of crops. Microorganisms including yeast, molds, and bacteria have been screened for their ability to modify or inactivate different mycotoxins. Few microorganisms with respective activity were isolated, the first was *F. aurantiacum* with the ability to detoxify aflatoxins. This organism has since then been studied extensively for possible degradation products. Apart from *F. aurantiacum*, a number of bacterial and especially fungal species have been found to detoxify aflatoxins. *Rhizopus* sp. has been claimed to be particularly suitable for large-scale detoxification of aflatoxin-contaminated feeds by solid-state fermentation. Ochratoxin A is rapidly degraded by microorganisms in the rumen to ochratoxin α (OTα) and phenylalanine. A yeast strain isolated from the hindgut of a termite, *Trichosporon mycotoxinivorans* also showed a potential deactivation of OTA to OTα and a metabolisation of zearalenone. The toxicity of DON is partially attributed to their 12,13-epoxide ring. Reductive deepoxidation could be achieved by ruminal and intestinal flora of pigs, hens, and rats or strain of *Eubacterium* isolated from bovine rumen. Enzymes capable of converting fumonisins to hydrolyzed fumonisin can be used to reduce the toxicity of this toxin (Grenier *et al.*, 2012).

Importantly, all measures aiming to remove or destroy mycotoxins in feeds may only become viable when each feed company considers that monitoring is a fundamental step in a mycotoxin control program. This has to be done by a consistent sampling program in the mass of grains received or to be purchased by the company, with regular analysis of mycotoxins. None of the control practices for toxins that have already been formed are efficient enough to completely reduce the losses caused in the animals; therefore, the implementation of any of these methodologies should be carefully evaluated from an economic standpoint.

Glossary

Aerobic Requiring the presence of air or free oxygen for life.
Cell-mediated immunity Immunity dependent on the recognition of antigen by effector T cells.
Granuloma Infiltration of a dense, macrophage-rich mass of cells.
Humoral immune response Antibody-mediated immunity.
Polymerase chain reaction test (PCR) Biotechnology to amplify specific portions of deoxyribonucleic acid (DNA) generating thousands to millions of copies of a particular DNA sequence.
Sensitivity Proportion of infected (diseased) individuals that test positive.
Specificity Proportion of noninfected (nondiseased) individuals that test negative.
Zoonosis Any infectious disease that is naturally transmitted between animals and humans.

The Disease

Bovine tuberculosis (bTB) is a chronic bacterial disease caused by the slow-growing, obligate intracellular bacterium *Mycobacterium bovis*. This pathogen has a worldwide distribution and, in several countries, bTB remains a major health problem in domestic livestock. The disease costs US$3 billion annually in global agricultural losses (Garnier *et al.*, 2003) and it is considered within the four most important cattle diseases globally (Finlay *et al.*, 2012).

Mycobacterium bovis is primarily a pathogen of cattle but it can also infect other mammals including badgers, possums, deer, goats, sheep, and camelids (Pollock and Neill, 2002; Scantlebury *et al.*, 2004; Skuce *et al.*, 2012). The bacterium is also able to affect humans, which makes bTB a relevant zoonosis that can spread through inhalation of infectious droplets and by ingestion of raw milk (Thoen and Barletta, 2006). In developed countries, eradication programs have significantly reduced the prevalence of this disease but, in some cases, reservoirs in wildlife make complete eradication difficult.

bTB primarily involves the respiratory system and associated lymph nodes. Infected individuals shed *M. bovis* in respiratory secretions, feces and milk, and occasionally in urine and vaginal secretions or semen, with large numbers of organisms shed in the late stages of infection. Most of the transmission occurs via aerosol circulation between animals that are in close proximity (Cassidy, 2006; Skuce *et al.*, 2012); however, indirect transmission through ingestion of contaminated feed has also been demonstrated (Neill *et al.*, 1994; Okafor *et al.*, 2011). Interestingly, Collins and Granje (1983) reported that, in experimentally infected calves, the minimum dose required to establish infection by the respiratory tract was up to 1000 times less than via the oral route. However, the oral route is likely most important in calves nursing infected cows (Neill *et al.*, 1994).

At present, *M. bovis* infection in cattle rarely appears as clinical disease. Instead, it is detected in apparently healthy animals, responding to any of the available diagnostic tests (Collins, 2006; Skuce *et al.*, 2012). When clinical signs are present they are nonspecific and, as bTB is a chronic debilitating disease, symptoms generally take months to develop. Loss of body condition, inappetence, and progressive emaciation may occur in advanced cases and respiratory signs may include chronic moist cough (especially during exercise) and thoracic abnormalities at auscultation. Lymph nodes may be enlarged, affecting contiguous blood vessels, airways, or the digestive tract. Mammary and reproductive tract involvement is rare and is usually accompanied by enlargement of associated lymph nodes (Divers and Peek, 2008).

bTB has a significant impact due to the cost of official control programs and represents an obstacle to domestic and international trade. Being a zoonotic pathogen, *M. bovis* has implications in human health, particularly in the developing world, although human disease due to this mycobacterium is now significantly less common than in the past decades (Biet *et al.*, 2005; Robinson *et al.*, 2012).

The Agent: The *Mycobacterium* Genus

Mycobacteria are members of the taxonomic group that includes the genera *Corynebacterium*, *Mycobacterium*, and *Nocardia* (CMN group) and the genus *Rhodococcus* (Cocito *et al.*, 1994). Mycobacteria are nonmotile and nonsporulated rods that are grouped in the suprageneric rank of *Actinobacteria* with a high guanine plus cytosine (G + C) content (61–71%) in the genomic DNA, and high lipid content in the wall; probably the highest among all bacteria. They also present several mycolic acids in the envelope structure that distinguishes the genus (Palomino, 2007).

These organisms include a number of major human and animal pathogens, comprising more than 100 species of obligate parasites, saprophytes, or opportunistic pathogens. Mycobacteria are structurally more closely related to Gram-positive bacteria; however, the genus does not fit into this category as the cell wall molecules are lipids rather than proteins or polysaccharides (Palomino, 2007). Thus, *M. bovis* is neither gram positive nor gram negative but is instead

 doi:10.1016/B978-0-444-52512-3.00194-7

described as acid-fast, and as once stained, it resists decolonization with acidified organic solvents (Lawn and Zumla, 2011).

The waxy coat confers the distinctive characteristics of the genus: acid fastness, extreme hydrophobicity, resistance to environmental exposure, and distinctive immunological properties. It also contributes to the slow growth rate of some Mycobacteria by restricting the uptake of nutrients (Palomino, 2007).

On the basis of genomic analysis, this group has been divided into two separate clusters, corresponding to the traditional fast-growing mycobacteria, represented by nonpathogenic environmental isolates, and the slow-growing mycobacteria, containing most of the overt pathogens (Harris and Barleta, 2001). Slow-growing mycobacteria of importance in human and veterinary medicine are found in two major complexes: *Mycobacterium tuberculosis* and *Mycobacterium avium*. The *M. tuberculosis* complex includes *M. tuberculosis*, *M. bovis*, *M. africanum*, and *M. microti*. *Mycobacterium tuberculosis* causes tuberculosis in man, primates, dogs, and other animals. *Mycobacterium bovis* causes tuberculosis in cattle, domestic and wild ruminants, man and other primates, and swine and other animals (Eglund, 2002).

The most relevant member of the slow-growing group, *M. tuberculosis*, is an obligate intracellular pathogen that can infect several animal species, although human beings are the principal hosts. It is an aerobic, acid-fast, nonmotile, nonencapsulated, nonspore-forming bacillus that grows most successfully in tissues with high oxygen content, such as the lungs. Compared with the cell walls of other bacteria, the lipid-rich cell wall is relatively impermeable to basic dyes unless combined with phenol (Lawn and Zumla, 2011).

However, the *M. avium* complex (MAC) consists of genetically similar bacteria including, among others, *M. avium* subsp. *avium* and *M. avium* subsp. *paratuberculosis*, which is the causative agent of Johne's disease in cattle. Microorganisms in this complex are opportunistic pathogens present in multiple locations; although human exposure to MAC is ubiquitous, most individuals rarely develop infection (St. Amand *et al.*, 2005). Relevant to animal health, *Mycobacterium paratuberculosis*, a pathogen for ruminants, is an obligate parasite unable to replicate in the environment (Eglund, 2002).

The unique cell wall in the *Mycobacterium* group enables the organism to persist in the environment and contributes to its resistance to low pH, high temperature, and chemical agents (Manning, 2001). *M. bovis* can survive for several months in the environment, particularly in cold, dark, and moist conditions. At room temperature, the survival time varies from 18 to 330 days, depending on the exposure to sunlight and the organism is infrequently isolated from soil or pastures grazed by infected cattle.

At the molecular level, the genetic configuration of Mycobacteria, in particular *M. tuberculosis*, has been the subject of extensive research. The sequencing of the *M. tuberculosis* genome has been a major advance to better understand the biology of the bacterium. Findings have allowed the subsequent identification of specific antigens for the development of diagnostics tests, multivalent vaccines, and biomarkers for tuberculosis (Lawn and Zumla, 2011). The discovery of genomic diversity help determine the factors involved in cellular growth and metabolism, virulence genes, and antibiotic resistance (Lamrabet and Drancourt, 2012).

Although there are many *M. tuberculosis* strains, studies of the phylogeny and ecology of *M. tuberculosis* have revealed six main strain lineages that are associated with particular geographical regions (Cole *et al.*, 1998; Lawn and Zumla, 2011). However, recent advances in mycobacterial genomics suggest that the amount of sequence variation in the *M. tuberculosis* genome might have been underestimated (Ford *et al.*, 2012) and that some genetic diversity have important phenotypic consequences. Indeed, the use of whole genome sequencing has shown significant heterogeneity in bacterial populations, even between strains with identical MIRU/VNTR, or RFLP patterns (Ford *et al.*, 2012).

As indicated by Rehren *et al.* (2007), the *M. bovis* and *M. tuberculosis* genomes show >99% identity at the nucleotide level. However, distinct phenotypes, virulence, and host range differentiate both pathogens, suggesting that distinctive mechanisms of gene expression might be involved in determining the differences between both bacteria (Rehren *et al.*, 2007; Garnier *et al.*, 2003).

Tuberculosis in Human Beings

Among communicable diseases, tuberculosis is the second leading cause of death worldwide, accounting for 1.7 million deaths each year. At present, the worldwide number of new cases is higher than at any other time in history. Most cases occur in low- and middle-income countries with increasing incidence in Africa and in the former Soviet Union and this trend has been related to the effect of HIV on susceptibility to tuberculosis (Frieden *et al.*, 2003; Lawn and Zumla, 2011).

Human tuberculosis is caused by *Mycobacterium tuberculosis* which is an obligate human parasite; though it can infect most mammals, no animals can reproducibly transmit infection to others. Consequently, the continued existence of *M. tuberculosis* depends on transmission among humans (Hunter, 2011). *Mycobacterium bovis* was responsible for approximately 6% of all human tuberculosis deaths in Europe where the practice of milk pasteurization was not yet implemented (Lawn and Zumla, 2011). However, mandatory pasteurization of milk and advances in public health made the prevalence of human tuberculosis due to *M. bovis* to decline dramatically in developed countries (Granje, 2001). Nevertheless, *M. bovis* is still classified as a risk 3 pathogen for public health (The Center for Food Security and Public Health, 2009; Thoen *et al.*, 2006).

A current concern related to human tuberculosis (TB) is the increased trend of multidrug-resistant tuberculosis that has been documented in a number of countries worldwide (WHO, 2004; Lawn and Zumla, 2011). Treatment for multidrug-resistant TB patients requires the use of second-line drugs for extended periods of time, with the disadvantage of a higher cost and toxicity, together with lower effectiveness compared with first-line drugs used for routine treatment of TB (Shah *et al.*, 2007).

Infection occurring in immunocompetent people when they are first infected is known as primary tuberculosis (Donald *et al.*, 2010). The infection spreads as caseating granulomas to regional lymph nodes and systemically for a

few weeks before regressing as immunity develops. Although the lesions may heal, the bacteria persist (Paige and Bishai, 2010). However, post-primary tuberculosis is typically restricted to the upper lobes of the lungs and a high proportion of cases recover spontaneously. However, those that become ill account for most of the transmission of the infection (Lawn and Acheampong, 1999; Hunter, 2011).

Definitive diagnosis of tuberculosis in human remains based on culture for *M. tuberculosis*, but rapid diagnosis of infectious tuberculosis by sputum smear for acid-fast bacilli is still a common practice (Frieden *et al.*, 2003). In countries with a high tuberculosis incidence the World Health Organization has recommended the use of automated systems based on liquid cultures. However, due to lower cost, traditional culture tests are predominant with some cases of false positives, although differentiation of *M. tuberculosis* from other mycobacteria is attempted on the basis of growth characteristics and specific biochemical reactions (Bekmurzayeva *et al.*, 2013).

The use of serological tests for diagnosis remains a challenge as they do not provide enough sensitivity and specificity to be used as a first-line screening tool. The most commonly used serological tests are immunochromatographic assays (ICAs) based on lateral-flow or flow-through analysis or enzyme-linked immunosorbent assay (ELISA) tests. However, detection of antibodies can lead to false positive results as antibodies against environmental mycobacteria are often present (Bekmurzayeva *et al.*, 2013).

Zoonotic Potential of Bovine Tuberculosis

As stated previously, in addition to its role in livestock disease, *M. bovis* is also responsible for some cases of tuberculosis in human beings. *Mycobacterium bovis* infection in humans was important in the late nineteenth and early twentieth centuries (Granje, 2001; Müller *et al.*, 2013), and accounted for a portion of human tuberculosis in Europe. However, nowadays the relevance of *M. bovis* as the cause of tuberculosis in humans remains and the bovine tuberculosis eradication programs, together with the pasteurization of milk, have been among the most successful campaigns against bacterial disease. In fact, human tuberculosis due to *M. bovis* is now very rare in developed nations and the completion of the bovine tuberculosis eradication programs was accompanied by a significant reduction in the incidence of human tuberculosis due to this bacterium (Cousins and Dawson, 1999; Robert *et al.*, 1999; Granje, 2001).

At present, *M. bovis* accounts for less than 1% of TB cases in humans. For example, in the United States, where differentiation between *Mycobacterium* spp. is routinely done among human patients, *M. tuberculosis* is responsible for approximately 98.6% of human infection and *M. bovis* only relates to 1.4% of the cases (Miller and Olea-Popelka, 2013).

Infection of human beings with *M. bovis* almost always occurs by inhalation of aerosols or consumption of milk containing the bacillus. *Mycobacterium bovis* was historically associated with extra pulmonary tuberculosis in infants, usually occurring due to the consumption of nonpasteurized milk from infected cattle (Thoen *et al.*, 2006). However, aerosols generated during the handling of tuberculous carcasses in slaughterhouses also pose a risk for infection with traumatic inoculation into the skin being a possible, but much less common, route of infection (Granje, 2001).

Currently, the main causes of concern related to human *M. bovis* are migration of individuals from regions where bovine tuberculosis is still prevalent, occurrence of *M. bovis* disease in immunosuppressed HIV-infected patients, epizootics in domesticated and wild mammals, and airborne-acquired *M. bovis* infection in animal keepers and meat industry workers (Thoen *et al.*, 2006). In addition, the number of cases of *M. bovis* in humans and animals may be underestimated or unavailable in some areas of the world, especially in developing countries (Miller and Olea-Popelka, 2013). In a recent study investigating the interphase between domestic cattle and humans, Torres-Gonzalez *et al.* (2013) administered tuberculin skin test and interferon-gamma release assay to 311 dairy farm and abattoir workers and their contacts linked to a dairy production and livestock facility in Mexico. The overall prevalence of latent tuberculosis infection was 76.2% by tuberculin skin test and 58.5% by interferon-gamma release assay, indicating an increased risk among those occupationally exposed to *M. bovis*.

At the present time, there are still questions concerning the relative virulence of *M. bovis* in human beings, the immunological consequences of infection without clinical signs, and the occurrence of human-to-human transmission of *M. bovis* (Lesslie, 1968; Granje, 2001).

Immune Response to Mycobacteria

The immune response to mycobacteria involves a complex sequence of coordinated events, attempting to clear the pathogen, but more likely leads to an adequate control of infection. The loss of control observed in some hosts may be due to genetic factors or may be caused by exogenous stressors such as immunosuppression, malnutrition, or secondary concurrent infections (Tiwari *et al.*, 2006).

After pathogen entry, mainly by the aerosol route, infection is initiated by macrophage phagocytosis where subsequent fusion of a lysosome with a phagosome creates the potential for intracellular destruction of the bacilli by acidification. However, virulent mycobacteria inhibit this fusion, preventing microbe destruction (Robinson *et al.*, 2012), which enables the bacterium to replicate and disseminate (Menin *et al.*, 2013).

The initial immunological response to infection includes the interaction of multiple cell types, leading to the development of a cell-mediated immune (CMI) response, characterized by delayed type hypersensitivity (DTH) and IFN-g production (Palmer and Waters, 2006). Once a CMI response is initiated, a granuloma forms around the infected macrophages by the interaction of immune cells and cytokines. The granuloma is a complex host-protective response to persistent mycobacterial stimuli to localize the infection and to prevent further dissemination (Robinson *et al.*, 2012) and consists of focal accumulation of inflammatory cells, such as multinucleated giant cells and lymphocytes (Menin *et al.*, 2013). The production of connective tissues around the granuloma is also critical for controlling both mycobacterial growth and tissue dissemination (Gil *et al.*, 2010).

Effective immune responses against *M. bovis* may be a result of several factors, such as strain resistance, infection route, and encapsulation of the tuberculous lesions by entrapping bacilli inside the lesions (Pollock and Neill, 2002; Volkman *et al.*, 2004; Gil *et al.*, 2010; Menin *et al.*, 2013). Consequently, progression of mycobacterial disease and survival of the host are dependent on the ability to limit mycobacterial growth by an effective granulomatous response (Menin *et al.*, 2013).

The development of immunity to mycobacteria involves the cooperative action of T lymphocytes as specific inducers and macrophages, but is not restricted to a cell-mediated response; both cellular and humoral responses work reciprocally through T helper type-1 and type-2 cells. In general, specific antibody responses are mostly detected late in the course of infection and correlate with severe progression of disease (Palmer and Waters, 2006). Therefore, as infection progresses with large numbers of bacilli, high antibody levels, and diminished cellular responses to antigens, a shift in the immune response from a proinflammatory and cytotoxic response to an antibody-based response occurs (Chiodini and Davis, 1993; Coussens *et al.*, 2004). Consequently, following the development of the CMI response, immunity develops further with the recruitment of B-lymphocytes (humoral immune response) and the production of antigen-specific antibodies (Pollock *et al.*, 2001). The balance between cell-mediated and humoral immune responses is considered to be a function of the dominant cytokines generated in response to the numbers of the pathogen within the host (Pollock *et al.*, 2006).

Diagnosis

Diagnostic tests for tuberculosis can be divided into two categories: those detecting the organism and those that evaluate the host response to infection. The first category includes, among others, smear and acid-fast stain, bacteriologic culture, and polymerase chain reaction test (PCR), which amplifies one or more specific DNA sequences, generating thousands to millions of copies (Bekmurzayeva *et al.*, 2013). However, indirect diagnostic is based on clinical signs, gross and microscopic pathology, and cellular and humoral immune responses (Maas *et al.*, 2013).

The microscopic demonstration of acid-fast bacilli in direct smears from clinical samples or tissues stained with the Ziehl/Neelsen stain, a fluorescent acid-fast stain, or immunoperoxidase techniques provides a presumptive diagnosis. However, confirmation requires additional testing. Bacteriologic culture remains one of the most important methods for tuberculosis diagnosis, despite the prolonged incubation time and the significant decontamination and biocontainment requirements (Robbe-Austerman *et al.*, 2013). Bacteriologic culture has high specificity and sensitivity and some modified automated mycobacterial radiometric culture devises, including the BACTEC system (Becton Dickinson Laboratories, Sparks, MD, USA), have been designed for human clinical laboratories. Among other advantages, these devises use liquid culture that provides a greater sensitivity. The two automated systems most commonly used are the BACTEC MGIT 960 System, which uses the MGIT 960 media (MGIT), and the BACTEC 460 TB System, which uses BACTEC 12B media (BACTEC). Although these media systems are comparable, the MGIT typically recovered more mycobacteria other than *M. tuberculosis* complex than the BACTEC, but had higher contamination rates (NRC, 2003; Robbe-Austerman *et al.*, 2013).

For more rapid identification, several PCR-based methods have been developed and assays targeting *M. tuberculosis*-specific sequences, including IS*6110* and the MPT64 gene, have been widely applied (Kim *et al.*, 2013). Specific sequences of DNA for diverse mycobacteria have been used as targets for PCR amplification and differentiation of bacteria of the *M. tuberculosis* complex from nontuberculous mycobacteria, as well as for specific differentiation of *M. bovis* from other members of the *M. tuberculosis* complex (Maas *et al.*, 2013). A well-validated probe for the *Mycobacterium* genus that targets the conserved sequence of the *rpo*B gene, which encodes the β subunit of RNA polymerase, is now available. This probe facilitates the identification of all *Mycobacterium* spp. and also distinguishes *Mycobacterium* spp. at the species level by restriction enzyme analysis (Lee *et al.*, 2000; Kim *et al.*, 2013).

As related to host reactions to infection, gross lesions observed postmortem in tissues, organs, and carcasses due to *M. tuberculosis* complex infection are based on the typical granulomatous appearance of tuberculous lesions (Maas *et al.*, 2013). In naturally infected cattle, tuberculous lesions are found most frequently in the dorsocaudal region of the lungs, often close to the pleural surface (Cassidy, 2006). In countries where the disease has been subject to longstanding control, lesions are found with higher frequency in the lymph nodes associated with the respiratory system (tracheobronchial and mediastinal) than in the lung parenchyma (Corner, 1994). However, in disseminated cases, multiple small granulomas may be found in numerous organs.

As cell-mediated immune responses are the first and strongest host response to mycobacterial infections, this category of tests is useful for early detection of MAP infection (Robbe-Austerman *et al.*, 2007). Among others, these include interferon-gamma assay and the tuberculin skin test. The interferon-gamma assay is a test based on production and release of IFN-g by sensitized bovine lymphocytes in response to *in-vitro* stimulation with a series of mycobacterial antigens. As cellular immunity is developed soon after infection, this test is considered the most sensitive during early infection (Collins, 1996; Stabel, 2001). Whole blood or peripheral blood mononuclear cells are incubated in the presence or absence of mycobacterial antigens (avian or bovine purified protein derivative (PPD) or other specific antigens of *Mycobacterium* spp) that induce previously sensitized T cells to produce IFN-g (Bekmurzayeva *et al.*, 2013; Maas *et al.*, 2013). Some studies have questioned the specificity of the IFN-g assay, indicating that the test is subject to cross-reactivity with other mycobacteria (Huda *et al.*, 2003). Although results from some studies suggest that the specificity values are moderate to low (Kalis *et al.*, 2003; de la Rua-Domenech *et al.*, 2006), some field trials have determined specificities as high as 94–100% (Palmer and Waters, 2006).

A widely spread diagnostic test based on the CMI response is the intradermal tuberculin skin test, which measures a DTH to mycobacterial antigens. The swelling formed 3 days after injection of a mycobacterial PPD is measured to determine the increase of skin thickness (Collins, 2006; Kalis *et al.*, 2003;

Maas *et al.*, 2013). The antigen in use is a protein derivative prepared from the heat-treated products of growth and lysis of *M. bovis* or *M. avium*. The derivative elicits a delayed hypersensitivity in an animal sensitized to microorganisms of the same species (Good and Duignan, 2011). The most common tuberculin tests in use today include the caudal fold test and the single intradermal test, which use only bovine tuberculin PPD and the comparative cervical test, which uses bovine and avian tuberculin PPD in combination (Monaghan *et al.*, 1994).

As an example of the use of this test in an official control program, in the United States, accredited veterinarians perform intradermal skin testing using 0.1 ml of PPD tuberculin into either of the caudal tail folds. After 72 h the test is interpreted as negative, suspicious, or positive. Suspicious or positive reactor cattle are retested by regulatory veterinary personnel by a comparative (avian and bovine PPD) cervical skin test (Divers and Peek, 2008).

The tuberculin skin test has long been the standard diagnostic test for tuberculosis in cattle (Welsh *et al.*, 2005), and remains the test of choice as prescribed by the OIE, with the IFN-g assay used as an alternative test (Schiller *et al.*, 2010). However, depending on test interpretation, stage and severity of disease, bTB prevalence, cross-reacting organisms and other factors, sensitivity and specificity are highly variable ranging from 52% to 100% and from 75.5% to 100%, respectively (de la Rua-Domenech *et al.*, 2006; Divers and Peek, 2008; Schiller *et al.*, 2010). In addition, a disadvantage of this test is a poor response in anergic animals, in advanced stages of the disease, in animals with confined infection in the udder or lymphatic nodes that has become latent, and in periparturient cows. Some cases exhibiting reactions to both avian and mammalian tuberculin may also occur (Good and Duignan, 2011).

The sensitivity of the skin test can be improved by increasing the potency of the tuberculin but this tends to raise the frequency of cross-reactions associated with sensitizations from other organisms such as *M. tuberculosis* and *M. avium* and other mycobacteria. As mentioned before, in the description of the United States' control program, in an effort to increase specificity, animals that test positive to the caudal fold test are tested 60 days later using the comparative cervical test that uses PPD bovis and a crude protein derivative from *M. avium* at adjacent sites on the neck. After 3 days, the swelling at each injection site is compared; when the inflammation caused by the PPD bovis injection site is greater than that caused by the PPD avium, the animal is considered *M. bovis* infected (Churbanov and Milligan, 2012). However, as reported by van Dijk (2013), a possible strategy to improve sensitivity is to increase the frequency of the analyses; however, risks of having more false positives together with an increase in the costs of control programs are important considerations.

Tests based on the host humoral immune response detect circulating antibodies against *M. bovis*. A positive test result may indicate the presence of infection, immunity to a previous infection, cross-reactions with antigens from other agents, the presence of maternal antibodies or antibodies present as a result of vaccination (Maas *et al.*, 2013). As progressive disease reduces the level of the cellular immunity and favors the initiation of a humoral response, serological assays are more sensitive after infection has progressed. Serological tests have some advantages in terms of logistics and they include ELISAs targeted to specific antigens and the lateral-flow immunochromatographic test, an animal-side test that uses a combination of multiple antigens (Lyashchenko *et al.*, 2006).

Epidemiology and Risk Factors

In the early twentieth century, bTB was found worldwide in cattle with a high prevalence in many countries. After an association between *M. bovis* infection in humans and the prevalence of tuberculosis in cattle was established, mandatory pasteurization of milk and advances in public health caused the prevalence of human tuberculosis due to *M. bovis* to decline dramatically, especially in developed countries.

Infectious diseases in general arise from an interaction between the infectious agent, the host, and a range of covariables, which may include other infectious diseases and the environment (Cassidy, 2006). Likewise, the transmission of *M. bovis* between cattle is dependent on a number of factors, including frequency of shedding, route of infection, infective dose, and host susceptibility (Griffin and Dolan, 1995).

Diseases transmitted between wildlife and livestock are particularly challenging. When a reservoir of infection exists outside the cattle population eradication becomes difficult (Corner, 2006; Munyeme *et al.*, 2009). In North America, it is estimated that at least 79% of diseases reportable to the World Organization for Animal Health (OIE) have a wildlife component (Miller and Sweeney, 2013). The several animal population interfaces at which *M. bovis* is present are characterized by unique population, climatic, ecologic, behavioral, and political factors (Van Campen and Rhyan, 2010). The test and slaughter policies of tuberculosis control, effectively used with domestic livestock, are insufficient in areas where wildlife reservoirs exist (Palmer, 2007) and disease eradication has been prevented by the presence of a wildlife reservoir of *M. bovis*. An example is provided by free-ranging white-tailed deer (*Odocoileus virginianus*) in Michigan, USA that represents the first known reservoir of *M. bovis* in free-living wildlife in the United States (O'Brien *et al.*, 2006; Palmer, 2007; Conner *et al.*, 2008; Wobeser, 2009). The bacterium persists for a week or longer on feedstuffs used as supplemental feed for deer (Palmer and Whipple, 2006) and deer-to-deer (Palmer *et al.*, 2004b) and deer-to-cattle (Palmer *et al.*, 2004a) transmission by indirect contact via feed has been demonstrated experimentally. In that area, several wildlife species besides white-tailed deer have been found positive for the organism (Bruning-Fann *et al.*, 2001), the most notable being coyotes (Bruning-Fann *et al.*, 1998), although these species are currently considered to be dead-end hosts for the infection.

As reviewed by Wobeser (2009), some other maintenance hosts in which infection persists through intraspecies transmission in the absence of an external source of *M. bovis* include the Eurasian badger (*Meles meles*) in Ireland and the United Kingdom; the brush-tailed possum (*Trichosurus vulpecula*) in New Zealand; African buffalo (*Syncerus caffer*), lechwe (*Kobus lechwe*), warthog (*Phacocoerus africanus*), and kudu (*Tragelaphus strepsiceros*) in Africa; and red deer (*Cervus elaphus*), and European wild boar (*Sus scrofa*) in Spain (Lees *et al.*, 2003; Palmer and Whipple, 2006; Renwick *et al.*, 2007; Naranjo *et al.*, 2008;

Bohm *et al.*, 2009). In these cases, mitigation strategies for TB management usually involve reducing density and exposure of the wildlife reservoir by increased hunting, eliminating supplemental feeding, and preventing contact between infected and at-risk populations. An additional potential strategy is the use of vaccination in wildlife or at-risk cattle, although, developmental work on vaccines is still underway and no effective vaccine exists for bovine TB at this time (Nol *et al.*, 2008; Palmer *et al.*, 2007; Robinson *et al.*, 2012; Menin *et al.*, 2013).

One of the main risk factors identified at the individual level is the age of the animals as life span associates with greater potential exposure time to the pathogen (Humblet *et al.*, 2009). Moreover, animals might get infected at a young age, but only develop a detectable immune response or express clinical disease when they are adults (Griffin *et al.*, 1996).

Differences in genetic resistance and susceptibility to bTB in cattle have been proposed. It is possible that in certain individuals nonspecific immunity could eliminate a low-dose *M. bovis* challenge before infection is established (Humblet *et al.*, 2009). In recent studies, a higher resistance to TB among *Bos indicus* than *Bos taurus* has been reported (Ameni *et al.*, 2007). Moreover, differences in susceptibility to the disease have been indicated for some genetic lines of cattle (Phillips *et al.*, 2002). As reviewed by Humblet *et al.* (2009), breed has been also identified as an individual risk factor for positive skin test. However, it is possible that the difference in susceptibility between breeds may be related to some degree to differences in management between diverse types of animals.

This variation in resistance to infection and disease caused by the *M. tuberculosis* complex seems to be under polygenic control (Allen *et al.*, 2010) and some candidate genes have been identified in the bovine and other species (Morris, 2007). More recently, Sun *et al.* (2012) investigated the role of host genetic factors in susceptibility to bTB in Chinese Holstein cattle and found the G1596A polymorphism in the toll-like receptor 1 (TLR1) gene to be associated with bTB infection status. Subsequently, Finlay *et al.* (2012) reported a genomic region on BTA 22 associated with tuberculosis susceptibility; this region contains the taurine transporter gene SLC6A6, or TauT, which is known to function in the immune system.

However, reported herd-level risk factors comprise a previous history of infection in the herd, presence of human cases, herd size (larger herds related to greater risk), type of production system (level of confinement and design of facilities), and management defining contact between cattle and contaminated environmental sources and wildlife (Humblet *et al.*, 2009). Other significant risk factors include purchasing animals (Gopal *et al.*, 2006; Kaneene *et al.*, 2002), animal movements (Gilbert *et al.*, 2005), and culling rate (Menzies and Neill, 2000).

Disease Control

Eradication of TB from cattle has been successful in several countries including Austria, Belgium, France, Canada, and most of the United States (de la Rua-Domenech, 2006). Traditionally, control efforts have included the removal of tuberculin reactors and suspect cattle (test-and-slaughter), execution of test-and-segregation methods, disinfection of premises, and the implementation of sound hygienic practices, followed by a periodic review of herd disease status using the tuberculin test and meat plant surveillance (Cassidy, 2006; Collins, 2006).

In general terms, there are different strategies and levels for disease detection. From the epidemiological perspective, surveillance aims at demonstrating the absence of disease and involves the systematic, continuous collection, and analysis of data on the health of wild animal species. Surveillance of cattle and wildlife in many developed countries aims to maintain a bTB-free status. Here, diagnostic assays are used to determine the presence of *M. bovis* in a particular area or population, rather than to determine exact prevalence (Maas *et al.*, 2013).

However, monitoring is restricted to known infected populations, and consists of the systematic recording of epidemiological data, with the specific purpose of detecting spatial and temporal trends, such as the spread, interspecies transmission, or the effect of management interventions in wildlife populations (Robinson *et al.*, 2012). Monitoring is often executed on a smaller scale than surveillance and, in general, is more invasive and expensive. Both surveillance and monitoring are used as a screening tool to determine whether the infectious agent is present in a defined population and area (Maas *et al.*, 2013). At another level, when testing individual animals and small populations for bTB, the assays have a short-term true diagnostic application, aiming at confirmation of the *M. bovis* infection status (Maas *et al.*, 2013).

Overall, official programs have focused on the control of animal movements (including the implementation of adequate animal identification and traceability), the detection of infected herds and individual animals, management of affected herds (including compulsory slaughter of reactors and herd depopulation), and the management of wildlife reservoirs (Collins, 2006). Combinations of tuberculin testing to detect infected animals, slaughterhouse monitoring, movement control, and destruction of exposed animals generally have been successful strategies. In the United States, slaughterhouse surveillance and subsequent traceback has been the main large-scale diagnostic strategy. However, a limitation of slaughterhouse inspection at the present time is the reduced

Glossary

Allostasis The ability of an animal to cope with physical and mental stress.
Animal welfare The current mental and physical states of an animal.
Distress A state of being when an animal can no longer cope with a stressor in order to maintain homeostasis that takes biological resources away from other biological functions.
Exsanguination An adjunctive method of euthanasia to ensure death in an unconscious animal. An incision is made on the throat and all blood vessels and sensory and motor nerves are transected.
Nonambulatory Weak, debilitated animals that are unable to stand or walk may be referred to as a Downer.
Pain A stressor that serves as a sensory or awareness of potential injury and tissue damage.
Stress A biological response from internal or external events, real or perceived, that disrupt homeostasis.
Stressor Stimulus or threat that elicits a stress response.
Unconsciousness A loss of individual awareness.
Zoonotic disease An infectious disease transmitted from animals to humans and from humans to animals.

Definitions

The term 'animal welfare' has been used by many in society and the media with various intentions of meaning. Much of the disagreement concerning the definition of the term lies in the mixing of the scientific and ethical questions of what animal welfare is. Even though the basis of the concept does have moral implications, this article will focus on the science of animal welfare. As more science on the welfare of animals is acquired, the definition of the term evolves but there are underlining concepts that remain consistent. The Bramble Committee (1965) was one of the first influential writings on animal welfare. It not only had a significant effect on how the world views animal welfare but also had a direct effect on legislative action taken regarding welfare in Europe. The Office International des Epizooties (OIE), commonly known as World Organization for Animal Health, defines an animal's welfare to be good if the animal: "is healthy, comfortable, well nourished, safe, able to express innate behavior and…. Not suffering from unpleasant states such as pain, fear of distress." (OIE, 2010). The Farm Animal Welfare Council (FAWC, 1993) identifies five areas that address the animal's physical and mental well-being when considering welfare. These areas are commonly referred to as the Five Freedoms (**Table 1**).

A more recent concept of animal welfare is based on allostasis, or the ability to cope with stress (McEwen and Wingfield, 2003; Korte *et al.*, 2007). This concept argues that the Five Freedoms are an unrealistic model for an animal's well-being because achieving all five would essentially be a state of 'utopia.' Most animals would naturally experience hunger, which stimulates their hunting/foraging behaviors. Thus, achieving one thing would be in direct conflict with another.

In scientific terms, animal welfare refers to the actual and current state of the animal (Keeling *et al.*, 2011). The scientific community seems to agree that welfare is a "characteristic of the animal, not something that is given to the animal" (Broom, 1996). Thus, individual animals experience varying degrees of welfare from good to bad. Bracke *et al.* (1999) state that the term describes "the quality of an animal's life as it is experienced by an individual animal." Curtis (2007) argued that an animal's state of being, not on how the animal feels, will be its rates of productive and reproductive performance relative to its predicted potential to perform.

The definition of animal welfare is evolving and the methods of how to precisely measure animal welfare as well as interpretations of state of being are likely to be debated for some time.

Stress is a biological response from internal or external events, real or perceived, that disrupt an animal's homeostasis. Threats can be perceived consciously or unconsciously (Carstens and Moberg, 2000). The stressor is the stimulus or threat that elicits a stress response. Stressors can be separated into two categories: by its duration as acute, chronic, or intermittent, and by type as psychological or physiological. Individual animals respond differently to stressors depending on age, health, genetics, and previous life experiences (Hahn and Becker, 1984), and they can easily adapt to stressors (Ladewig, 2000). Pain is a type of stressor that serves as an awareness of potential tissue damage. Noxious stimulus allows an animal to remove itself from or react to the stimulus in order to reduce or avoid the damage (Carstens and Moberg, 2000; Molony and Kent, 1997).

There are four main biological responses to a stressor initiated by an animal: autonomic nervous system, neuroendocrine, immune and behavioral, to cope with a stressor, and elicit a stress response (Moberg, 2000). Animals have adapted mechanisms to cope with stress, similar to humans, so stress is not always a bad thing. Moreover, stress is not always harmful to the body and it helps to maintain homeostasis. For example, the biological response to a stressor can promote memory of the situation in order to avoid it in the future

Table 1 The five freedoms and provisions

Freedom from thirst, hunger, and malnutrition	Free access to freshwater and a diet to maintain full health and vigor
Freedom from discomfort	Providing a suitable environment, including shelter and a comfortable resting area
Freedom from pain, injury, and disease	Prevention or rapid diagnosis and treatment
Freedom to express normal behavior	Providing sufficient space, proper facilities, and company of the animal's own kind
Freedom from fear and distress	Ensuring conditions that avoid mental suffering

Source: Adapted from Webster, A.J.F., 2001. Farm animal welfare: The five freedoms and the free market. Veterinary Journal 161, 229–237.

(McEwen, 2005). However, if the stressor is severe and the animal can no longer sufficiently cope with the stressor to maintain homeostasis, it must then take biological resources from other biological functions and stress becomes distress (Moberg, 2000; Carstens and Moberg, 2000). It is when an animal experiences distress that its well-being becomes compromised. Understanding an animal's physiology, psychology, and behavior can help scientists make educated assessments of the animal's well-being (Broom and Johnson, 1993).

Global Perspective

Attention to animal welfare varies considerably around the world. Generally, the EU has the strongest laws and attention to farm animal welfare among nations. However, individual member countries in the EU have stronger animal welfare rules than the EU as a whole. Some European countries that are not a member of the EU such as Switzerland have strong farm animal welfare laws. As a general rule in Western Europe, the more Northern countries have stricter animal welfare laws than more Southern European countries.

The United States and Canada have some farm animal welfare laws and regulations. Most laws are related to humane slaughter. Transportation of farm animals in the United States must not exceed 28 h. Handling of animals in stockyards are covered by the US Packers and Stockyard Act.

Within the United States, several states have laws to prevent certain production practices. For example, Florida, Arizona, and California have banned gestation crates for pregnant sows. Some state initiatives have also banned cages for laying hens and crates for veal calves.

Asia, Africa, and Latin America have few animal welfare laws or regulations. They may impose international standards (e.g., for the EU) if they export to countries that request for a higher animal welfare standard.

Retail companies that sell animal products include grocery stores, restaurants, and food service companies. Some 'retailers' have animal welfare standards that impact production practices, whereas some have specific requirements for production standards. A search of each retail company's website often yields their animal welfare standards. The retailers often drive change more quickly than through legislation. Activist organizations have learned that pressure on retailers can lead to changes more quickly than through legislation.

One critical question has arisen in recent years about global standards for animal welfare. Most standards are minimum requirements. Some people feel that an animal welfare standard must accomplish a high level of animal welfare. Standards vary around the world based on many factors, including target level (minimum through high); scientific interpretation; geography and unique production methods; cultural differences; and different ethical, moral, or religious standards. The OIE has minimal standards that are accepted by member countries of the World Trade Organization. Otherwise, animal welfare standards vary considerably from no standards through high standards.

Farm Animals

One of the most common issues and concerns with standard agriculture practices is the pain and distress it causes the animal. These practices are performed to improve the overall well-being of the animal, but may have both human and animal implications. Scientists are continually researching improved and more humane methods for standard agricultural procedures. The standard practices of the agriculture industry and the regulations and requirements that must be followed for their use in production and research are discussed immediately below by species, and some recommendations are provided. As stated in the Guide and the Care and Use of Agricultural Animals in Research and Teaching, all basic biological needs should always be met such as food, water, shelter, and even comfort.

Cattle

Castration

Castration has multiple purposes in several male species, primarily to reduce aggression and therefore limit harm to handlers and other animals, satisfy food quality regulations in order to ensure a high-quality eating experience for consumers, and to manage reproductive and genetic control. Several methods of castration in cattle are acceptable in the Ag Guide, for example, surgical or bloodless castration, rubber rings, and tubing bands. When deciding on a method the animal's age and weight should be accounted for, and performed before 2 or 3 months of age or below 230 kg (Farm Animal Welfare Council, 1981) when the procedure is least stressful. At weights greater than 230 kg, local and topical anesthetics should be used to minimize pain.

Castration increases the cortisol response (Robertson *et al.*, 1994), substance-P concentrations (Coetzee *et al.*, 2008), haptoglobin concentrations (Ballou *et al.*, 2013), and abnormal behaviors (Robertson *et al.*, 1994; Currah *et al.*, 2009), whereas it suppresses leukocyte concentrations (Ballou *et al.*, 2013) in calves. The specific castration method used (surgical or bloodless) can cause increased pain. The bloodless castration methods are associated with both acute and chronic pain that can last up to 42 days (Molony *et al.*, 1995; Thüer *et al.*, 2007), and should only be used when surgical castration is not appropriate for research protocols or when

postoperative complications are expected. All ages of castration cause acute pain, but cortisol concentrations were greatest in calves surgically castrated at older ages (Robertson *et al.*, 1994).

Pain relief in the form of a local anesthetic and nonsteroid antiinflammatory drug (NSAID) increased appetite and reduced the cortisol response (Sutherland *et al.*, 2013), and prevented leukocytosis, neutrophilia, and leukocyte suppression (Ballou *et al.*, 2013) in surgically castrated calves. Administering local anesthesia before castration may reduce acute pain; however, it does not eliminate it (Thüer *et al.*, 2007).

Dehorning

Dehorning in cattle is performed to reduce injury to handlers and animals, and reduce bruising of carcasses and damage to hides. Injury to other animals caused by horns is especially high during transportation. The United States currently does not have any regulations for disbudding and dehorning, but the AVMA (2013b) recommends disbudding as the preferred dehorning method in calves with the use of local anesthetics and NSAIDs at the earliest age practicable. Polled breeds eliminate the need for dehorning and disbudding, and should be used when possible.

Disbudding occurs with a heated disbudding iron or chemical paste when the horn buds are 5–10 mm long, approximately 8 weeks of age (Stafford and Mellor, 2005). Amputation dehorning causes a greater cortisol response than cautery or chemical disbudding with cautery having the lowest response and the preferred technique (Stafford and Mellor, 2011). There are no differences in cortisol response between the four different amputation dehorning methods: scoop, guillotine shears, saw, or embryotomy wire (Sylvester *et al.*, 1998a), suggesting that all amputation methods of dehorning are stressful in calves.

The cortisol response using a scoop method of dehorning was elevated for 3–4 h postdehorning (Sylvester *et al.*, 1998b) or as long as 7 h (McMeekan *et al.*, 1998a, 1998b). Local anesthetics reduce the peak cortisol response to scoop dehorning but as soon as the drug wears off, concentrations increase as if no local anesthetic had been applied. More than just local anesthetic is needed for long-term pain from dehorning. Local anesthetic maintains cortisol concentrations 5 h after dehorning, but then it remains elevated for up to 10 h after dehorning (Sutherland *et al.*, 2002a; McMeekan *et al.*, 1998b). Local anesthetic plus cauterizing the wound (Sylvester *et al.*, 1998b; Sutherland *et al.*, 2002b), administering a second treatment of local anesthetics during the period of pain (McMeekan *et al.*, 1998a), or administering both the local anesthetics and a NSAID (McMeekan *et al.*, 1998b) will reduce cortisol concentrations to levels comparable to controls. However, the type of drugs used may not have the appropriate mechanism of action to alleviate the pain caused from dehorning. The NSAID, ketoprofen, worked with local anesthetic, but phenylbutazone did not reduce the cortisol response (Sutherland *et al.*, 2002a).

Abnormal or pain behaviors also increase after dehorning. Head shaking and tail and ear flicking increased after dehorning, but administration of a local anesthetic reduced those behaviors, however, for only 2 h after dehorning (Sylvester *et al.*, 2004). Sutherland *et al.* (2013) also observed that calves dehorned spent more time head shaking and ear flicking, as well as less time eating. Head shaking was reduced and eating increased when local anesthetic and the NSAID banamine were given, but ear flicking behaviors did not change. Calves injected with the NSAID meloxicam and a local anesthetic nerve block showed reduced ear flicking for 44 h, head shaking for 9 h, and displayed less pain sensitivity 4-h postdehorning (Heinrich *et al.*, 2010).

Methods should be used to minimize pain and distress, especially in older animals. The use of both a local anesthetic and an NSAID alleviate the pain for a longer period of time across multiple breeds of cattle.

Identification

Several methods of identification are used in cattle: ear and tail tags, ear notches, back tags, tattoos, electronic identification, branding, and paint marks. Most of these forms of identification are not permanent and the type of identification should be appropriate for the farm and research protocols. However, permanent methods of identification should be used in order to trace the origin of individual production animals in order to protect the agriculture industry and public health (AVMA, 2013c). States in the United States have brand registries and regulations related to branding, but only Montana, Nevada, Oregon, and Idaho require hot-iron branding applied to cattle imported from Canada and Mexico (AVMA, 2011).

The only two methods of permanent identification are hot-iron and freeze branding. Hot-iron branding burns the skin to leave a scar, whereas freeze branding kills pigment-producing cells found in the hair follicles so that the hair is depigmented when it grows back. Cattle that are hot-iron branded have a greater cortisol response (Schwartzkopf-Genswein *et al.*, 1997a), high epinephrine concentrations (Lay Jr. *et al.*, 1992a), show more pain behaviors of tail-flicks, kicks, falls, and vocalizations (Schwartzkopf-Genswein *et al.*, 1997b, 1998), but no differences in sensitivity to touch or in stress-induced analgesia are found between hot-iron and freeze branding (Schwartzkopf-Genswein *et al.*, 1997a). Hot-iron branding causes greater distances and velocities of head movements and forces on the headgate and chute (Schwartzkopf-Genswein *et al.*, 1998). Hot-iron branding also causes more tissue damage than freeze branding, with freeze branding showing more inflammation through infrared thermography early after branding and hot-iron having a prolonged inflammatory response (Schwartzkopf-Genswein and Stookey, 1997). Dairy calves, however, showed a different response with no differences in cortisol, epinephrine, and norepinephrine concentrations between hot-iron and freeze branding, but hot-iron branded cows exhibited a greater escape avoidance reaction and had increased heart rate (Lay Jr. *et al.*, 1992b).

The physiological, behavioral, and inflammatory responses of cattle indicate that hot-iron branding causes more pain or discomfit than freeze branding, and therefore freeze branding is the preferable branding technique regardless of breed. However, other alternatives should be used for branding if possible. No research has studied administered pain relief during branding, but to minimize pain and discomfort this should be considered.

Euthanasia

Humane methods to alleviate or eliminate pain and distress that immediately results in unconsciousness should be carried out during euthanasia. When animals are sick, injured, or suffering for any reason that continued life is not a humane option or is worse than death, then the owner or veterinarian should euthanize the animal. This process is for the sake of the animal's welfare and quality of life. Acceptable methods of euthanasia consistently result in a humane death by (1) direct depression of neurons that are required for life, (2) hypoxia, or (3) physical disruption of brain activity. The AVMA Guidelines on Euthanasia (AVMA, 2013a) lists several methods of euthanasia appropriate for ruminants.

Several criteria have been listed by the AVMA for evaluating humane euthanasia methods: (1) ability to induce loss of consciousness and death with a minimum of pain and distress; (2) time required to induce loss of consciousness; (3) reliability; (4) safety of the personnel; (5) irreversibility; (6) compatibility with intended animal use and purpose; (7) documented emotional effect on observers or operators; (8) compatibility with subsequent evaluation, examination, or use of tissue; (9) drug availability and human abuse potential; (10) compatibility with species, age, and health status; (11) ability to maintain equipment in proper working order; (12) safety for predators or scavengers should the animal's remains be consumed; (13) legal requirements; and (14) environmental impacts of the method or disposition of the animal's remains.

The use of barbiturates is an acceptable method of euthanasia; however, large amounts of drug are required in larger animals so cost may deter its use. Barbiturates must also be administered by a person who is registered with the US Drug Enforcement Agency and under veterinarian supervision. Residues remain in the tissue and animals euthanized with barbiturates; therefore any drug that leaves residues cannot be used for human consumption unless approved by the US Department of Food and Drug Administration. Physical methods of euthanasia using gunshot or penetrating captive bolt (see **Figure 1**) are most commonly used in cattle. Physical methods disrupt and destroy the brain tissue. Additional action after rendering an animal unconscious should be taken to ensure death. Intravenous administration of potassium chloride or magnesium sulfate can be used in animals not to be consumed or exsanguination after physical euthanasia are methods to ensure death, but neither can be used as a sole method of euthanasia. After euthanasia, death must be confirmed by lack of heartbeat, respiration, and corneal reflex along with rigor mortis before rendering the animal.

Tail docking in dairy cattle

Dairy cattle are tail docked in order to increase udder and milk hygiene. However, tail docking is seen as an animal welfare issue because of the pain it causes from performing the procedure, as well as effects on communication between the herd and with caretakers, and because it alters fly avoidance behavior. The United States has no regulations regarding tail docking of cattle; however, the AVMA (2013d) does not support it and state that if amputation is medically necessary then a veterinarian must perform the procedure. Regulations and policies regarding tail docking cattle vary from country to country. It is prohibited in Denmark, Germany, Scotland, Sweden, UK, and some Australian states but a veterinarian can perform the procedure and only for reasons of udder health. In New Zealand, where the practice originated it must be performed by a veterinarian using a rubber ring, and Canada opposes the practice but a trained person can perform the procedure in young calves (Stull *et al.*, 2002).

Two different methods of docking are used, a rubber ring or docking iron (for review of methods and implications see Stull *et al.*, 2002). Banding with a rubber ring makes the tail necrotic and it detaches 3–7 weeks postbanding, or will be manually detached after 7 days, especially in older calves and heifers. Inflammation may be more severe if the band is placed on the vertebra and not over the joint. If the band is placed too close to the base of the tail then the blood vessels in the tail may not constrict, so it is recommended to band distal to the sixth coccygeal vertebrae (Gregory and Matthews, 1998). The docking iron amputates the tail with a heated scissors-like tool.

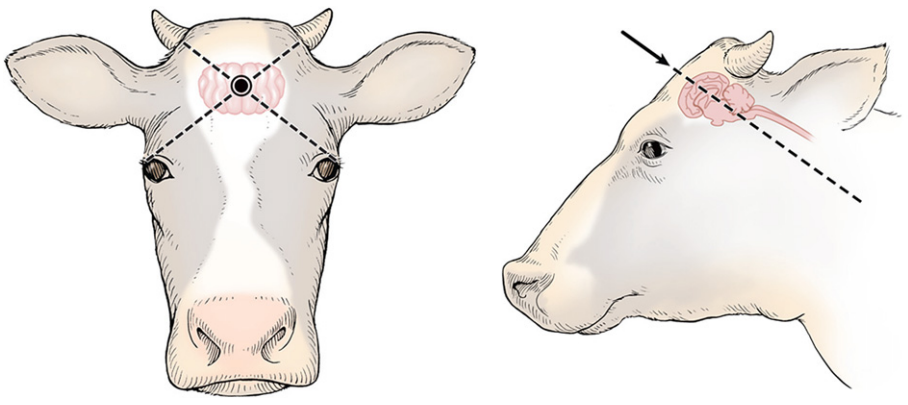

Figure 1 Anatomical landmarks for penetrating captive bolt or gunshot physical methods of euthanasia. The intersection of the dotted lines indicated with a circle in the front view (a) is the proper point of entry. The side view (b) dotted line shows the trajectory through the brain. Reproduced from Shearer, J.K., 2013. Humane Euthanasia of Sick, Injured and/or Debilitated Livestock. Ames, IA: Iowa State University. Available at: http://vetmed.iastate.edu/HumaneEuthanasia (accessed 21.08.13).

The cortisol response (Petrie *et al.*, 1996; Eicher *et al.*, 2000; Schreiner and Ruegg, 2002a) and immune response (Eicher and Dailey, 2002; Eicher *et al.*, 2000, 2001) are not different between docked and control handled dairy heifers and calves. The rubber ring method may be preferred because hemorrhaging can occur when using the docking iron (Petrie *et al.*, 1996), but Tom *et al.* (2002) found that the rubber ring method caused an increase in cortisol concentrations 1 h after banding, but the docking iron did not. So there is some conflict as to which docking method is better and causes the least distress.

Behavioral changes in docked cattle indicate there is some discomfort experienced from tail docking. Increased activity is found 2 h postbanding in docked calves compared with controls (Eicher and Dailey, 2002). Tail grooming increased up to 5 days after docking, and increased frequencies of standing and lying the first day have been seen in rubber ring docked calves with no differences between the docking iron treatment and controls (Tom *et al.*, 2002). Tail docked heifers are also sensitive to heat and cold, showing greater changes in the tail surface temperature and increased stomping activity (Eicher *et al.*, 2006).

Besides the acute stress of removing the tail, the other potential welfare issue from tail docking in dairy calves is the inability to remove flies. More flies are present on docked cows and fly avoidance behaviors increase. Docked calves lick and ear twitch more frequently than control calves that tail swing more frequently (Eicher and Dailey, 2002). Cows that were tail docked had a greater count of flies in the rear legs and foot stomping increased as an alternative fly avoidance behavior (Eicher *et al.*, 2001). Udder cleanliness and contamination to milking equipment and milk is another reason dairy cattle are tail docked. Eicher *et al.* (2001) found docked cows were cleaner, but Schreiner and Ruegg (2002b) found no differences between docked and undocked cows in somatic cell counts, intramammary infection, and udder and leg cleanliness.

No benefits to the animal's welfare have been observed with tail docking. Behavioral changes and sensitivity to hot and cold temperatures suggest that the procedure causes discomfort even if physiological parameters do not indicate stress. Fly avoidance behaviors change with cattle not using their tail as much to remove flies; therefore, more flies are present at the rear of the animal, and little differences are found in the cleanliness of docked and undocked cows. With no consistent and obvious benefit to the animal, it is suggested that tail docking be discouraged.

Hoof care in dairy cows

Dairy cow lameness causes economic loss to the produce because of milk production and fertility losses, and is the primary reason for culling cows. Lameness is painful and increases sensitivity to mechanical noxious stimuli (Whay *et al.*, 1997). The type of diseases causing lameness influences the pain threshold as well. Whay *et al.* (1998) found sole ulcer and white line disease pain thresholds were still reduced 28 days after treatment but acute digital tissue infection did not.

Many producers find it hard to detect lameness at early stages because cows do not show behavioral responses to the pain until the injury is advanced and behavioral changes are obvious (O'Callaghan, 2002). Pain changes the gait of the animal and is the most common system to detect lameness. The FASS (2010) lists the gait changes to look for: (1) arching of the back if rear limb lameness, (2) shortening the stride length of the affected limb as to reduce the time weight bearing on the limb, (3) sinking the dew claws on the unaffected contralateral limb as weight is transferred to the unaffected limb, (4) head bob in a vertical plane because the head raises when the affected limb hits the ground, (5) slower walking speed and more frequent stops, and (6) swinging the affected limb in or out depending on the location of the lesion.

A five-point numerical rating system (NRS) (**Table 2**), with one being sound and five severely lame, is used to assess an animal's gait that producers should be trained on. This lameness system emphasizes posture and gait (Sprecher *et al.*, 1997). The NRS has been found to be a better predictor of ulcers causing lameness than increased lying behavior or walking speed that is also found in lame cows. The NRS was able to predict the appearance of ulcers 4 weeks before diagnosis (Chapinal *et al.*, 2009).

A lameness score greater than two is a risk factor for extended intervals between conception, more service per pregnancy, and increased likelihood of being culled (Sprecher *et al.*, 1997). Milk yield in cows can be reduced 4 months before the cow is diagnosed with lameness and up to 5 months after treatment, with a mean reduction of 360 kg per lactation period (Green *et al.*, 2002). It is important that producers detect lameness as soon as possible in order to treat the cows to improve health and welfare of the animal, but also to reduce economic loss to the producer. Improvements made to the flooring cattle walk on can also improve welfare in lame cows. Flower *et al.* (2007) observed that high-friction composite rubber surfaces provided secure footing and comfort during walking for cattle with and without sole ulcers. Preventative care also helps reduce the prevalence of lameness in dairies. Claw trimming is performed usually once a year in the dry off period, and hooves are trimmed and treated at any point lameness is detected. Foot baths of copper sulfate, zinc sulfate, or formaldehyde are also recommended to control bacteria.

Swine

Housing

Pigs are social animals and should be housed in groups in production systems. Isolation has shown to increase cortisol production and shift leukocyte percentages (Ruis *et al.*, 2001) in pigs. It is common to see group-housed growing pigs in production, typically in groups of 2–30 pigs per pen, but groups of hundreds and thousands are becoming more common (FASS, 2010). Mixing unfamiliar pigs does increase social stress, which affects the physiology and immune system (Morrow-Tesch *et al.*, 1994). Fighting for dominance in larger groups typically lasts 48 h (Meese and Ewbank, 1973) after mixing, then once the hierarchy is established the group remains relatively stable. Hides (structures for animals to put their head in) are one alternative to allow submissive pigs to protect their heads and ears in order to escape aggressive attacks in order to improve their own well-being during mixing

Table 2 The five-point numerical rating system to assess lameness in dairy cows

Score gait	*Description*	*Behavioral criteria*
1. Sound	Smooth and fluid movement	Flat back Steady head carriage Hind hooves track up Joints flex freely Symmetrical gait All legs bear weight equally
2. Imperfect gait	Imperfect locomotion but ability to move freely	Flat or mildly arched back Steady head carriage Hind hooves do not track up perfectly Joints slightly stiff Slightly asymmetric gait All legs bear weight equally
3. Mildly lame	Capable of locomotion but ability to move freely is compromised	Arched back Steady head carriage Hind hooves do not track up Joints show signs of stiffness Asymmetric gait Slight limb
4. Moderately lame	Ability to move freely is diminished	Obvious arched back Head bobs slightly Hind hooves do not track up Joints are stiff and strides are hesitant Asymmetric gait Reluctant to bear weight on hurt limb but still uses it in locomotion
5. Severely lame	Ability to move is severely restricted and must be encouraged to move	Extremely arched back Obvious head bob Poor tracking up with short strides Obvious joint stiffness with no flexion, hesitant and deliberate strides Asymmetric gait Inability to bear weight on one or more limbs

Source: Adapted from Flower, F.C., Weary, D.M., 2006. Effect of hoof pathologies on subjective assessments of dairy cow gait. Journal of Dairy Science 89, 139–146.

or spontaneous fighting outbreaks (McGlone and Curtis, 1985).

Five days before parturition, sows are moved into farrowing stalls. In nature, sows will leave the group 24–48 h before birth to seek isolation and build a nest. Some degree of confinement is therefore necessary in production and preferred by the sow (Phillips *et al.*, 1991). The farrowing system should minimize piglet mortality, provide thermal comfort for both sow and offspring, and accommodate normal behaviors when possible (FASS, 2010). The farrowing crate is designed to reduce piglet injury and protect handlers from aggressive sows, but sow movement is restricted. Sows in farrowing pens are more active, but the piglet suckling duration is longer in the crate, and piglet mortality significantly increases in the farrowing pen (Blackshaw *et al.*, 1994). The farrowing crate is more beneficial to the production and well-being of the piglets.

Individual and group-housed gestation systems are similar in production and animal welfare if the systems are managed properly. Each housing system has its own advantages and disadvantages (McGlone *et al.*, 2004). Each system should minimize aggression and competition during feeding and mixing and allow sows to express normal behaviors (AVMA, 2005). Gestation crates have been banned in the EU and are phasing out in the United States in some states (e.g., Florida, Arizona, and California) after the first 30 days of gestation. The US states with the most pigs have not banned the gestation crate. It is important that good management practices are used in group housing systems as sow welfare will be compromised by social stress and feed competition. Smaller groups (35–40 sows) should be maintained in static groups, whereas larger groups (80–200) in dynamic groups in order to minimize social stress, and different feeding systems: drop-feeding, trickle-feeding, and electronic sow feeding systems, or stalls for individual feeding can be used to minimize feeding competition (FASS, 2010). A review of the recent scientific literature (McGlone, 2013b) essentially agrees with the earlier reviews (McGlone *et al.*, 2004; Rhodes *et al.*, 2005) that sow welfare overall is equivalent based on science in well-managed group pens or gestation crates.

Castration

Pigs are castrated at an early age to reduce boar taint, a foul smelling odor and flavor in meat caused from androstenone and skatole, reduce aggression toward other pigs and handlers, and to control for unwanted pregnancies at market age. Castration causes acute pain-induced distress that can reduce nursing and increase vocalizations and pain-like behaviors making it an animal well-being concern (McGlone *et al.*, 1993). Painful production procedures without the use of

Table 3 Methods of euthanasia approved for different sizes of pigs

Euthanasia method	*Age and size of pig*			
	Suckling pig	*Nursery pig*	*Grower–finisher pig*	*Mature pig*
	Up to 5.5 kg	*Up to 32 kg*	*Up to market weight*	*Sows and boars*
Carbon dioxide	Yes	Yes	Yes but not practical	Yes but not practical
Gunshot	No	Yes	Yes	Yes
Penetrating captive bolt	No	Yes	Yes	Yes
Nonpenetrating captive bolt	Yes	Yes with secondary step	No	No
Electrocution from head to heart	Only for pigs >4.5 kg	Yes	Yes	Yes
Electrocution in head only	Only for pigs >4.5 kg	Yes with secondary step	Yes with secondary step	Yes with secondary step
Anesthetic overdose	Yes	Yes	Yes	Yes
Blunt trauma	Yes	No	No	No

Source: Adapted from National Pork Board, 2008. On-farm Euthanasia of Swine: Recommendations for Producers. Des Moines, IA: National Pork Board.

anesthetics and analgesics are an increasing public concern. Alternatives include slaughtering pigs at younger ages before reaching sexual maturity, immunocastration techniques, and genetic selection for females. Studies using local, general, and topical anesthetics and analgesics have found no reduction in the pain-induced distress of castration as measured by cortisol concentrations, immune function, and substance-P (Sutherland *et al.*, 2010, 2012). The use of anesthetics may temporarily reduce cortisol concentrations from castration but once the drug wears off, typically 30–60 min after the procedure, the cortisol concentrations raise to similar or higher levels than pigs castrated without anesthetics. It has also been found that 3 days after castration, pigs castrated with an analgesic and both anesthetic and analgesic had higher cortisol concentrations than pigs castrated without pain relief (Sutherland *et al.*, 2012).

Immunocastration blocks gonadotropin-releasing hormone thereby reducing luteinizing hormone, follicle-stimulating hormone, testosterone, androstenone, and skatole (Zamaratskaia *et al.*, 2008). Immunocastration occurs later in life so increased lean growth and improved gain: feed of the boar is maintained longer (Dunshea *et al.*, 2001). One concern with immunocastration is the safety of handlers from aggressive boars, but few differences were found between physically and immunologically castrated pigs in a pig–human interaction test although immunocastrated pigs interacted with humans more (Guay *et al.*, 2013). Handling during transportation to slaughter showed significantly less vocalizations and fewer dead and down pigs in immunocastrated pigs compared with physically castrated pigs (Guay *et al.*, 2013). Immunocastration may improve male pig well-being and production economics.

Euthanasia

There are six acceptable methods of euthanasia for pigs of different ages and sizes in 'On-Farm Euthanasia of Swine – Recommendations for the producer' developed by the National Pork Board and American Association of Swine Veterinarians. When a pig is ill or injured a decision based on the best interest of the well-being of the animal should be made for treatment or euthanasia. Euthanasia may be best if the pig has not improved after 2 days of intensive care, it is severely injured or nonambulatory with the inability to recover, or the pig is immobilized. Euthanasia methods either first render the pig permanently insensible and results in death, or renders the pig insensible and requires a secondary step to achieve death (Table 3).

Sheep/Goats

Herd management

Welfare strategies concerning sheep and goats are focused on the typical topics: housing, nutrition, health, and mental well-being. Personnel giving daily care to animals should be familiar with sheep and goat behavior, signs of illness as well as potential health treatments so that they can prevent injury and disease. Sheep and goats should be fed to maintain a body condition score (BCS) of at least a 1.5 on a 1–5 point scale (FASS, 2010). Sheep are particularly sensitive to copper (Cu) toxicity, and therefore, copper should be considered when formulating diets with special consideration to the Cu concentration in available forages. Care should be taken to prevent Johne's disease (paratuberculosis), which can be transmitted from infected ewes on supplementing with raw colostrum from an infected ewe.

Shearing can be stressful as it can not only induce fear by restraint and handling but also from the heat and noise of the shears. In addition, sheep may acquire lacerations during the shearing process; thus, it is suggested that shearing should only be done by trained professionals. Time of shearing should be taken into account and sheep should have access to shelter from severe weather and environmental conditions (freezing temperatures, cold rain, extreme wind, or sun without shade) after shearing if needed. Shearing ewes before lambing can increase birth weights of lambs (Kenyon *et al.*, 2006a,b). Newborn lambs may find it easier to nurse without obstruction when ewes are sheared. If management or weather prevents the shearing of ewes, a common practice of removing wool from the dock and udder (crutching) can be done.

Mulesing is a procedure developed to reduce the incidence of fly strike on particularly wrinkled skin breeds of sheep such as the Merino breed. This procedure involves removing excess skin to prevent flies from laying eggs in soiled folds of skin. However, the procedure is considered painful and is highly criticized. Thus, mulesing is no longer practiced in most countries.

Tail docking and castration

Tail docking and castration are standard husbandry practices that are regularly performed on lambs. It is suggested that these be done as early in life as possible (preferably before 2 weeks of age) considering the lamb is established and healthy. Tail docking is done to prevent fly strike from long tails becoming excessively soiled with manure and urine, attracting flies. Acceptable methods for tail docking and castration include the use of rubber rings, emasculators, surgical removal, and hot iron cautery for tail docking or various combinations of these methods (Battaglia and Mayrose, 1981; Smith *et al.*, 1983; Ross, 1989; ASIA, 2002). Very short tail docking is discouraged due to the increased incidence of rectal prolapse (Thomas *et al.*, 2003). The use of rubber band/rings without corresponding anesthetics or denervation with emasculator has been shown to elicit more behavior indicating pain (Wood *et al.*, 1991; Sutherland *et al.*, 1999). The EU, Australia, and New Zealand consider tail docking and castration after a certain age, a surgical procedure and require the use of anesthetics (Defra, 2013; FASS, 2010).

Behavior

Sheep and goats are very herd oriented. When handling, performing routine herd maintenance and when transporting, animals should be kept in groups to prevent injury to animals and humans by sheep and goats attempting to escape or regroup with the herd. Sheep and goats are trainable to load and can be handled in restraint devices such as a squeeze chute table (Grandin, 1989), head stanchions (Sheldon *et al.*, 2006), manual methods (Battaglia, 1998), and the Panepinto sling (FASS, 2010).

Euthanasia

As in cattle, barbiturates, gunshot, and captive bolt are approved methods of euthanasia followed by exsanguinations, or administration of potassium chloride or magnesium sulfate to ensure death. Electrocution may also be used as a method of euthanasia but restraint and proper placement of the electrodes make electrocution an unlikely option for research and field use (AVMA, 2013a).

Poultry

Housing

There are several housing systems available for poultry: conventional and furnished cages, aviaries, littered floors, and free range. Regardless of the housing system it should allow for the cleaning of equipment and inspection of the birds without handling them, although the birds should be easily accessible (FASS, 2010). No system is stress free. Hens in floor housing have social hierarchies and cannibalistic pecking is a serious welfare concern. In caged hens this seems to be more prominent in extreme crowding when feeding competition is a problem, and in noncaged systems because of the larger group sizes. If group size is too large, hens display escape and fear behaviors (Craig and Adams, 1984).

Systems with similar characteristics have similar welfare problems (Lay Jr. *et al.*, 2011). Conventional cages do not meet behavioral needs of nesting, perching, and dust bathing, and restrict movement, but cannibalism and pecking is less frequent because of the small group sizes. Osteoporosis and claw problems are also more prominent. The EU banned conventional cages in 2012 and the only cages allowed are furnished cages. In complex systems such as furnished cages, or noncaged systems, bone fractures increase because of more movement and expression of behaviors, but bone quality is better (Tactacan *et al.*, 2009). Noncaged and outdoor systems provide litter or soil that meet behavioral needs of the animal but disease and parasites are problematic. An increased repertoire of behaviors does not mean they all benefit the well-being of the animal, as cannibalism and smothering occurs more in larger areas and larger groups. The larger group sizes in these systems also allows for disease to be more easily spread because of the difficulty to clean the system. Prelaying behavior, duration of dust bathing and feather, foot, and claw damage are improved in alternative systems. Perches, however, do lead to keel bone depressions (Appleby *et al.*, 1993). Even with longer periods of dust bathing observed in alternative systems, it does not prevent feather pecking, but resulted in increased foraging behavior (Huber-Eicher and Wechsler, 1997).

Egg quality in laying hens may also be compromised or altered depending on the housing system, which is of economic concern to the producer. Outdoor housing leads to great fluctuations in the external and internal quality of the egg (Van Den Brand *et al.*, 2004). However, Tactacan *et al.* (2009) found no differences in egg production, egg weight, or cracked and soft-shelled eggs between laying hens in conventional and enriched cages, but enriched cages did have 'dirtier' eggs. No one system is completely stress free and each has its own health and welfare advantages and disadvantages.

Forced molting

Natural molting replaces the plumage after sexual maturity in poultry. During this time egg production is paused and can be out of sync with the flock, so commercial production operations force molt in order to synchronize molting, rejuvenate the flock, and extend production by 2 or 3 laying cycles (FASS, 2010). Forced molting is done by reducing day length and withdrawing feed and water from laying hens.

Forced molting increases eosinophils, total white blood cells, monocytes, and packed cell volume (Brake *et al.*, 1982). It also decreases liver, ovary, oviduct, and body weights (Brake and Thaxton, 1979). However, greater amounts of weight loss is associated with more eggs, egg weight, specific gravity, and shell weights (Baker *et al.*, 1983), and nonmolted hens perform poorly in egg quality and production (Zimmermann and Andrews, 1987; Lee, 1982). The practice of forced molting not only benefits the industry by increasing egg production and quality but also reduces the number of male chicks and hens euthanized annually and rejuvenates feathers improving thermoregulation in hens (FASS, 2010).

Beak trimming

Beak trimming is performed in poultry production to reduce cannibalism, aggressive behaviors, and feather pecking (for review see: Cunningham, 1997). This is an economic advantage for the producer, but a welfare concern for the animal. The sensory receptors are cut from the tip of the beak, and sensory

deprivation and pain reduces activity, food intake, preening, and pecking (Hughes and Gentle, 1995; Duncan *et al.*, 1989). Beak trimming should only be performed in young chicks, 1 day old, with proper equipment to minimize pain, excessive bleeding, and infection, and to promote rapid healing (AVMA, 2013e). The earlier the chick at trimming, the less likely the neuromas to form. The beak heals rapidly and grows back but shorter than nontrimmed birds and with no afferent nerves or sensory corpuscles (Gentle *et al.*, 1997).

Several methods of beak trimming exist (AVMA, 2010 Welfare Implications of Beak Trimming). Mechanical techniques use a scissor-like device like secateurs to cut the tip of the beak. The traditional hot blade method cuts and cauterizes the edge of the beak destroying the tissue adjacent to the cut. This blade technique can either be hot or cold. Electric current can be used to damage the beak to shed the tip. The robotic infrared beak-trimming device applies an infrared light beam across the tip of the beak to destroy the living basal tissue. Little or no differences have been found in the welfare of chicks between systems. Henderson *et al.* (2009) did find infrared trimmed chicks were heavier at 11-days old compared with hot blade and nontrimmed chicks, but by 21 days there were no longer differences. Gentle and McKeegan (2007) also found reduced weights compared with nontrimmed chicks, but the hot blade compared with infrared trimmed chicks were smaller and had the least amount of beak regrowth, but no differences have been found between a hot or cold blade in the traditional method (Gentle *et al.*, 1997). When consequences of trimming method performed at an early age was evaluated later in laying hens, no differences were observed in egg production, body weight, or stress physiology. The infrared method did reduce aggression and improve feather condition though suggesting it as a better welfare alternative to the hot blade method (Dennis *et al.*, 2009).

Health and Nutrition

Proper management is paramount to the well-being and health of the herd. An effective health strategy for any type of species can relate to the same basic principles: good biosecurity, trained and perceptive personnel, and good communication among animal caretakers including the veterinarian. When animals, especially breeding stock, are brought to the new production facility they must be quarantined from the existing herd until the health of the incoming animals has been evaluated and found acceptable by the veterinarian. Depending on the species and the types of zoonotic diseases the incoming animals may have been exposed to, quarantine may range from preintroduction testing and simple observation to an extended isolation of new animals under strict observation. Appropriate vaccinations as well as external and internal parasite programs also need to be in place. A list of zoonotic diseases of agricultural animals is listed in the FASS (2010). In addition to an immunization schedule, preventative health also includes routine daily health checks of the animals and facilities, maintaining safe, clean living conditions with appropriate environmental levels.

Good nutrition, in general, encompasses individual animals receiving the nutrients required for the particular classification they fall into as well as proper management of transition from one classification to another (e.g., lactating to nonlactating). Requirements of nutrients, including water, will vary with season, diet, and physiological status (NRC, 2007b). Male animals fed diets of concentrates should be formulated for a calcium to phosphorous ratio of at least 2:1 to help prevent urinary calculi. Osteoporosis in laying hens is common leading to cage layer fatigue, bone fractures, and even paralysis. Hens deficient in calcium, phosphorus, and vitamin D are more susceptible and increased activity can reduce the prevalence of osteoporosis (Webster, 2004). All classes of animals should have as much clean water as they feel the need to drink. Water should be checked daily for contaminants. Dental maintenance is also an important factor in nutrition. Animals that are kept into adulthood such as breeding stock and horses can develop dental problems that make consumption and digestion of feed difficult. Geriatric horses who have worn most of their dental reserve crown are often fed softer, pelleted feed to promote the breakdown and digestion of feed. Some animals are not naturally thrifty and cannot seem to maintain a desirable body condition score. Consideration of these animals should involve the decision to either feed them separately, or with a group of similar animals that need an increased nutritional plan. In extreme cases of inability to assimilate feed, for whatever reasons, euthanasia should be considered to prevent the animal from suffering unnecessarily. A very comprehensive detail of the nutrient requirements of animals can be found in NRC (1996) for beef cattle; NRC (2001) for dairy cattle; NRC (1998) for pigs; NRC (1994) for poultry; NRC (2007b); for horses, and NRC (2007a) for sheep and goats.

Handling and Transport

Handling animals during routine husbandry practices should be performed in a careful, considerate, respectful, and calm manner. This positive interaction with animals will make them calmer and easier to handle (FASS, 2010). It is important when working with animals to know their flight zone (**Figure 2**) as they move more easily when they can see the handler angled from the shoulder (Grandin, 1980, 2011). The flight zone varies by animal and how calm it is, with a larger flight zone in more excited animals and calmer animals having a smaller flight zone. It is best to remain calm and quiet during handling as loud noises can be stressful and cause animals to baulk.

There are several different styles of equipment used to move animals. If the facility is designed well, no equipment may be needed and the natural behaviors of the animal can be used to move them. Flags, paddles, and boards and panels (**Figure 3**) are designed to be used with the natural movement of the animal and to minimize stress to the animal. Electric prods should only be used in specific situations on the hindquarters when all other attempts to move the animal have been made, and less than 10% on ranches or feedlots.

Many US regulatory agencies, such as the US Department of Agriculture (USDA), Department of Transportation, Centers for Disease Control and Prevention, and Food Safety and Inspection, govern animal transportation to ensure the humane transport and prevention of the transmission of communicable

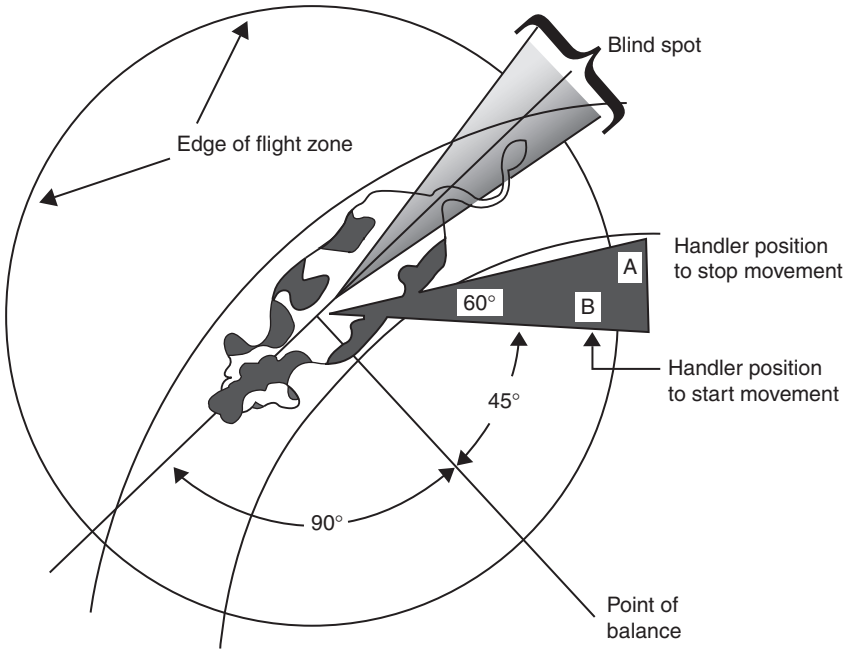

Figure 2 Flight zone showing how to effectively move an animal. Adapted from Figure 1 in FASS, 2010. Chapter 5: Animal handling and transport. In: Guide for the Care and Use of Agricultural Animals in Research and Teaching, third ed., p. 46. Champaign, IL: Federation of Animal Science Societies. Available at: http://www.fass.org/page.asp?pageID=216 (accessed 15.01.14).

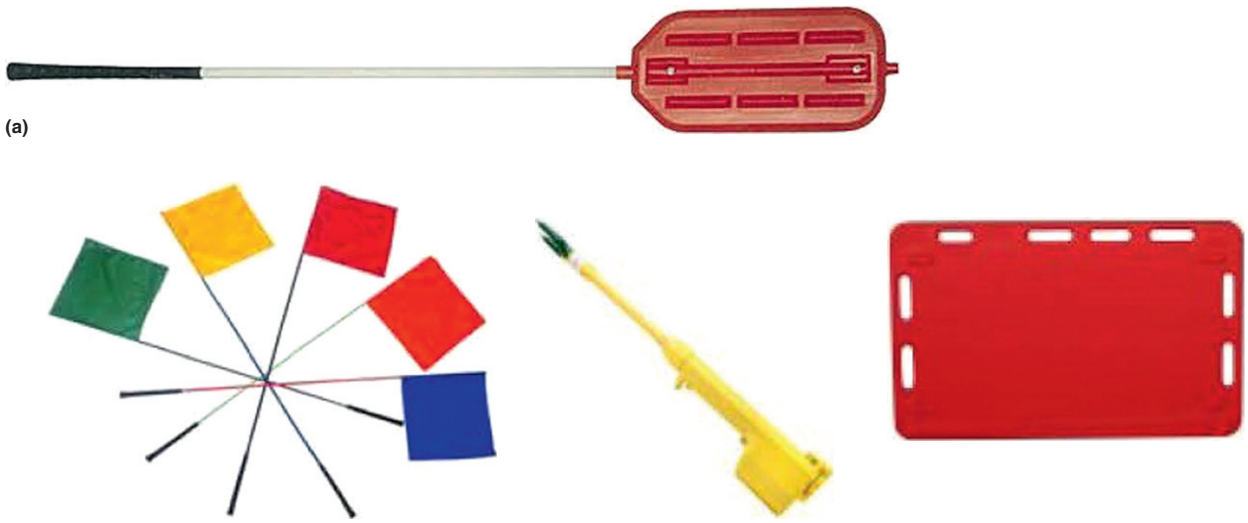

Figure 3 Livestock handling and sorting equipment: (a) rattle paddle, (b) flag, (c) electric prod, and (d) sort board/panel. Products (a) and (b) are provided by Koehn Marketing, Inc. and products (c) and (d) are distributed by QC Supply.

diseases (ILAR, 2011). Transporting livestock is a stressful event because it involves handling, loading, unloading, novelty, mixing or isolation, weaning, inability to maintain balance, motion sickness, feed/water deprivation, and temperature fluctuations, among other factors (FASS, 2010). As so many factors are present during transportation, it is hard to discern the most stressful component, therefore every factor of transportation should be accounted for and overall well-being of the livestock considered, reducing stress from transportation. To do so, calm handling methods should be used, and trailers should be designed to minimize slipping, protect the animal from environmental stressors, and provide adequate space per head (**Table 4**; National Pork Board, 2008).

The 28 h law regulates the maximum time animals are able to be held in trailers without food, water, and rest before being unloaded. After 28 h of transportation, animals must be

Table 4 Minimum space allowances during transportation for different livestock species

unloaded into pens provided with provisions for at least 5 h (US Code: 49 USC Sec. 80502, 2012). When transporting livestock across state lines or between countries, all federal regulations for vaccinations, veterinary inspections, and health certificates must be in compliance. The Humane Methods of Livestock Slaughter Act (US Code: 21 USC 601, 2012) also states that animals should be minimally excited during loading/unloading, transportation, and handling. Nonambulatory animals should be isolated from ambulatory animals and moved with carts, sleds, canvas tarpaulins, or slide boards. They may not be dragged, hoisted, or dropped. If the animal cannot be moved it should be humanely euthanized on the spot (FASS, 2010). Once animals are unloaded after transportation to a slaughter plant they are moved to lairage pens where water is provided. Animals must have enough room to lie down without being on top of each other, and given a minimum period of rest of 1 h for cattle and 2 h for pigs.

Humane Slaughter

Animals must be killed (also called slaughtering or harvesting) and the carcass processed before human consumption. Animals have been killed for human food since animals were first domesticated more than 10 000 years ago. The method of slaughter in the European and American custom is meant to be humane. EU requires that food animals be "killed in a way that avoids unnecessary suffering." The US legislation that governs animal harvest is the Humane Methods of Slaughter Act of 1958; referred to as the Humane Slaughter Act or HSA). The HSA requires that animals are rendered rapidly insensible before being shackled or cut.

Another method of slaughter is ritual slaughter for Jewish and Muslim faiths. In ritual slaughter, the animal is not rendered insensible before being shackled or cut. Ritual slaughter is considered not humane by some people, but is required by the customs of people of certain religions, and therefore is acceptable.

Transport and handling before stun and exsanguination is also the subject of animal welfare concern. Extensive guidelines are provided by Temple Grandin, the AMI, and others.

Table 5 Recommended minimum space requirements for group-housed small animals (ILAR, 2011)

Animal	*Weight (g)*	*Floor area/animal (cm^2)*	*Height (cm)*
Mice	<10	38.7	12.7
	Up to 15	51.6	12.7
	Up to 25	77.4	12.7

Chimpanzees			
Juveniles	Up to 10	1.4	152.4
Adults	>10	≥ 2.32	213.4

Laboratory Animals

Laboratory animals used for research and teaching should be housed with adequate space (**Tables 5** and **6**) and resources that meet their physiological and behavioral needs (ILAR, 2011). Social animals should be housed in pairs or groups that allow for social interaction unless the research protocol does not allow for social contact. Environmental enrichment should

be utilized in order to improve animal well-being. Types of enrichment vary depending on the species, but it should facilitate exercise, manipulative activities, and cognitive challenges that improve psychological well-being. Animals should be habituated to novel environments and procedures to reduce stress associated with the procedures.

Wildlife

Wildlife mammalian research involves the collection of mammals in the field in order for scientists to understand community and population dynamics, genetics, anatomy and physiology, ecology and diseases (ASM, 1987). Kill traps should have low probability of capturing nontarget animals and kill the animal quickly. Live traps should keep the animal alive and uninjured. Live trapping may be painful or distressful to the animal especially when trying to escape, so padded traps may be more humane (Bekoff, 1995). Pitfalls can be used for both live and dead captures, but should have enough food to sustain the animal until the next trap check or enough liquid to drown the animal quickly. Humane methods should be used during euthanasia. Gases (carbon dioxide and ether), thoracic compression or cervical dislocation, and shooting if it causes instantaneous death are approved methods that should be used when appropriate for the animal.

Taking samples of tissue should be in a way to minimize pain. If it is a short procedure anesthetics may not be used in order to release the animal quickly, but longer more painful procedures should end in euthanasia of the animal. Marking the animal for reidentification should be done with minimal pain and should not restrict the natural movements of the animal, and should be suitable for the length of the study.

When using amphibians and reptiles in research, care must be given to the unique husbandry practices. Thermoregulation is difficult to satisfy because heat uptake and loss is from the environment, and light intensity must match the temperature of the environment. Shallow water containers or daily spraying and hiding places are appropriate for their habitats (Pough, 1992).

Animals in Exhibits and for Recreation

Zoos and Aquariums

Zoos and aquariums are regulated by the Animal Welfare Association (AWA), federal, state, and local laws. In the United States, public animal exhibits must be licensed and inspected by the USDA Animal and Plant Health Inspection Service (APHIS). Inspections are conducted yearly by APHIS as well as when credible complaints are filed. If species of animals housed are listed on the Endangered Species Act (ESA), the facility must also adhere to regulations set by the ESA. The ESA was passed by the Congress in 1973 with the purpose of protecting the species of animals at risk of extinction as well as to protect the ecosystems which they depend on for survival. The US Fish and Wildlife Service is responsible for the regulation of terrestrial and freshwater animals, whereas the National Marine Fisheries Service is responsible for marine wildlife. There are two classifications animals can be listed under within the ESA. Animals listed as endangered are defined as in danger of extinction, and animals listed as threatened are defined as a species that are likely to become endangered in the foreseeable future. All species of animals except pest insects are eligible to be listed in the ESA. North American institutions can volunteer to apply for accreditation with the Association of Zoos and Aquariums to certify that they meet high standards of physical and emotional needs (AZA, 2013). Zoos and aquariums have guidelines for general health and well-being that includes habitat and enrichment requirements, detailed record keeping of all general care, emergency care, custodial care, breeding, staff/human interactions, and a biosafety program to protect all animals and humans from zoonotic diseases. Inspections are performed every 5 years by a subcommittee of three experts in animal care and zoo management, and then reviewed by a panel of 12 before accreditation is awarded. International regulation is overseen by the Convention of International Trade of Endangered Species of Wild Flora and Fauna (CITES), who regulate the trade and movement of approximately 5000 species of animals. Participation in CITES is currently voluntary.

Fairs, Stock Shows, and Rodeos

The AWA requires those who exhibit animals to the public for compensation must obtain a license with USDA and APHIS; however, the AWA exempts certain groups from Federal regulation. Privately owned pets and those who exhibit animals in agricultural events such as fairs, stock shows, and rodeos are exempt from the AWA. These productions are, however, regulated by state and local laws. There are some regulated activities often found at events such as these including exhibition of large/big cats and nonhuman primates, elephant rides, camel rides, and petting zoos. Moreover, exhibitors who train, handle, or own animals used in film or television, or perform in a circus are regulated.

Rodeos are also subject to state and local laws; however, most rodeo associations have rules and regulations for animal welfare written into their bylaws. Both the Professional Rodeo Cowboys Association (PRCA) and the National Intercollegiate Rodeo Association (NIRA) have rules regarding the care and treatment of rodeo animals. Violations of rules can result in disqualification in addition to monetary fines for offenders. Rules are enforced not only by the judges but also officials appointed within organizations to ensure that policies are being followed. Both PRCA and NIRA judges undergo training and certification on specific rules and are familiar with the behavior and physiology of animals used in rodeo events. PRCA judges also communicate with the designated veterinarian regarding any health concerns with the animals. All PRCA rodeos are required to have a veterinarian on-site during the event. All contracted animals are required to be inspected before each event and are required to be withdrawn if they are deemed unfit by the judge or veterinarian. Both the PRCA and the NIRA require animal stock contractors to be approved and in good standing to be allowed to contract their animals to a sanctioned event. Contracted animals, such as the cattle for roping events, have minimal weight requirements. No contracted animal is allowed to perform more than once a day.

Competitors observed by rodeo officials using unnecessary roughness either in the arena or on the grounds can be disqualified or fined. The PRCA has an Animal Welfare Committee that meets regularly to review rules and make recommendations to the Board of Directors concerning animal welfare issues. They are regulated by the AWA but do fall under state and local laws as well as the rules and regulations set forth by the show associations to which the competitor is participating in.

There are many different horse show associations, for example, PRCA and NIRA.

Horse Racing and Dog Racing

Racing is regulated by laws that are set by the state in which the track or meet is located. Owners and trainers of animals are typically required to acquire a license in all states they wish to participate in. Most states require that each racing association have an established racing commission. Racing commissions are typically in charge of maintaining rules and regulations, including the welfare of the animals involved. The presence of an on-site track veterinarian who works under the jurisdiction of the racing commission is required to maintain veterinary reports, monitor use and testing for drugs, and suitability to compete on race day. A Commission veterinarian typically maintains several 'lists': (1) the Veterinarian's List of horses and/or dogs that the veterinarian deems unfit to race due to illness, physical distress, lameness, or another medical condition or (2) a Bleeder's List of horses that have exhibited external signs of exercise-induced pulmonary hemorrhage after a workout or race as observed by the commission veterinarian. Bleeders usually undergo an ineligible, recovery period that progressively lengthens for each incidence, and are often barred from racing after repeated bouts of pulmonary hemorrhage.

Horse Shows

Horses exhibited in a public display, in competition, except events where speed is the prime factor, such as rodeo events, parades, and organized trail rides are regulated by APHIS under the Horse Protection Act (HPA) of 1970. The HPA is focused on the Tennessee Walking Horse industry to prevent the practice of soring, which is stimulating a horse to step higher by intentionally rendering a horse unsound by physical or chemical means. Even though the HPA focuses on soring, it could be applied, or easily amended to include other aspects of the equine industry. It has been proposed to amend the HPA to include the transport of horses for the purpose of slaughter illegal. Larger horse show organizations have implemented their own animal welfare statues as proactive measures in support of the human treatment of horses. Regulations include the testing for controlled substances, altering tail function to minimize tail swishing, appropriate footing, and checkpoints for endurance horses. There are also many tack and equipment rules and regulations among show associations. In 2012, the American Quarter Horse Association received its first report from its newly formed Animal Welfare Commission with regard to identify issues that negatively affect the welfare of horses as well as recommendations to define and prevent inhumane treatment of horses.

Conflicting Societal Issues and Pressures

Many people are interested in improving animal welfare. Some improvements in animal welfare may have negative consequences for other societal issues (McGlone, 2001). For example, when pigs or poultry are outdoors, they may be exposed/inoculated with Salmonella and influenza. These zoonotic exposures would be minimized by use of indoor housing (McGlone, 2013a). Animal welfare changes should be considered in the context of other societal issues such as food safety, environmental pollution (including greenhouse gases), worker health, safety, and community impacts and economics.

Asian Aquaculture

F Corsin, IDH, The Sustainable Trade Initiative, Hanoi, Vietnam
K Yamamoto, University of Stirling, Stirling, UK

Glossary

Aquaculture The farming of aquatic organisms, including fish, mollusks, crustaceans, and aquatic plants, with some sort of intervention in the rearing process to enhance production, such as regular stocking, feeding, protection from predators, etc. Farming also implies individual or corporate ownership of the stock being cultivated.

Domesticated In a broader sense, animals selected from the wild adapt to a special habitat created for them by humans, bringing a wild species under human management. In a genetic context, process in which changes in gene frequencies and performance arise from a new set of selection pressures exerted on a population.

Feed conversion ratio (FCR) Ratio between the dry weight of feed fed and the weight of yield gain. It is the measure of the efficiency of conversion of feed to fish (e.g., FCR=2.8 means that 2.8 kg of feed is needed to produce 1 kg of fish live weight).

Food and Agriculture Organization (FAO) An agency of the United Nations that leads international efforts to raise levels of nutrition, improve agricultural productivity, better the lives of rural populations, and contribute to the growth of the world economy.

Mariculture Cultivation, management, and harvest of marine organisms in the sea, in specially constructed rearing facilities (e.g., cages, pens, and long lines).

Small-scale aquaculture Aquaculture system with a small annual production (max 1 tonne per unit and 10 t total) made of one or more small production units, run by a family or communally, and requires low to moderate input levels and limited external labor; the motive may be own food supply.

Trash fish/low-value fish Fish that have a low commercial value by virtue of their low quality, small size, or low consumer preference – they are either used for human consumption (often processed or preserved) or used for livestock/fish, either directly or through reduction to fishmeal/fish oil.

Aquaculture – A Brief History

In 2013 more fish ('fish' is a collective term used for mollusks, crustaceans, and any aquatic animal that is harvested (FAO Fisheries Glossary, see 'Relevant Websites' section)) were farmed than beef (Marshall, 2013), which was the outcome of years of steady growth in the production of aquatic animals, aquaculture (Figure 1). The history of aquaculture goes back to thousands of years. Records show that fish farming was first described by Fan Lai in *'The Treatise of Pisciculture,'* in China, around 460 BC. Although the abundance of fish in seas and rivers and the lower population did not justify the intensive farming of fish, as seen for other forms of animal protein production, in recent decades an explosion in aquaculture production has been seen (Figure 2). Since 1950, when the FAO started keeping statistics of aquaculture production 1950, aquaculture has grown 130 times (i.e., 600 thousand metric tons in 1950 to 80 million metric tons in 2011), with a global average annual growth rate of 8.32% since 1950 or 7.72% since 1961 (FAO, 2013a–c). Compared with beef or poultry during the same time (i.e., since 1961), the annual growth over the past 50 years was of 1.64% and 4.98%, respectively (FAO, 2013a–c; Table 1).

But why such incredible growth in the production of farmed fish? There are many reasons for it:

- Although there have been some marked changes in catch trends depending on countries, fishing areas, and species, overall global capture fisheries production continue to remain stable at approximately 90 million metric tons (FAO, 2012), thus creating the need to satisfy the demand for seafood.
- The benefits of eating seafood and its cherished omega-3 became increasingly known for reducing risks of heart disease and supporting brain development of children during gestation and infancy (FAO/WHO, 2011).
- The demand for seafood did not remain constant, but it grew steadily with a growing population and its gross domestic product (GDP) (i.e., people prefer to eat more fish as they get richer). The calculated apparent fish consumption was 123 million metric tons in 2009, where 67.8% of that was consumed in Asia. China accounts for approximately half of Asian seafood consumption and slightly more than one-third of global consumption (Figure 3). Fish consumption significantly varies among countries (Figure 4).
- Technology has made the production of seed (in the form of fingerlings or postlarvae or other earlier life stage used to stock farming units) in captivity; hence, the domestication of many aquatic animals is increasingly possible. Domestication enables better control over quantity and quality of seed for aquaculture without depending on collection of wild seed and hence improves the efficiency and sustainability. Table 2 provides the number of domesticated aquaculture species, illustrating some differences between each phylum, and a total of 37% of all aquacultured species domesticated to date (Benzie *et al.*, 2012).
- Table 3 highlights that fish are also efficient converters of feed. The average feed conversion ratio (FCR) to produce

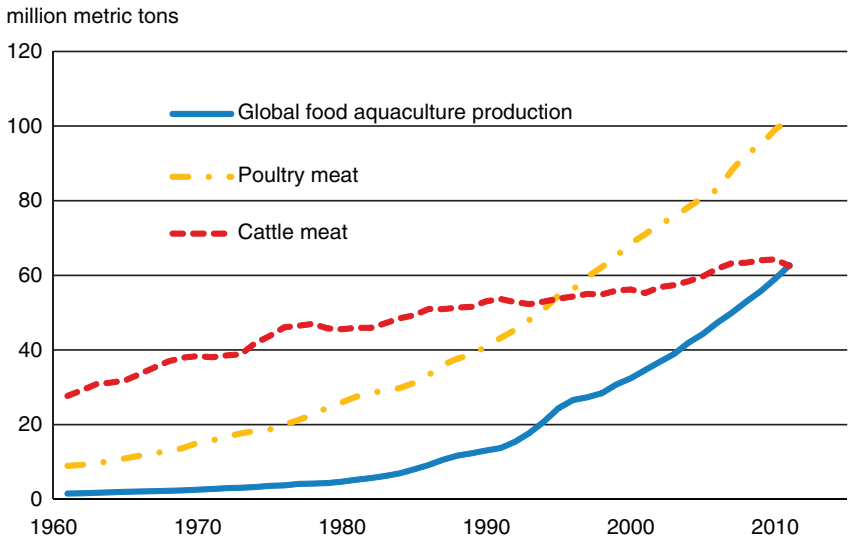

Figure 1 Global production of cattle meat, poultry, and food fish from aquaculture between 1961 and 2011. Reproduced from FAO, 2013a. Aquaculture and Capture Production 1950–2011. Available at: http://www.fao.org/fishery/culturedspecies/Pangasius_hypophthalmus/en (accessed 08.04.14); and FAO, 2013c. FAOSTATS. Available at: http://faostat.fao.org/site/291/default.aspx (accessed 08.04.14).

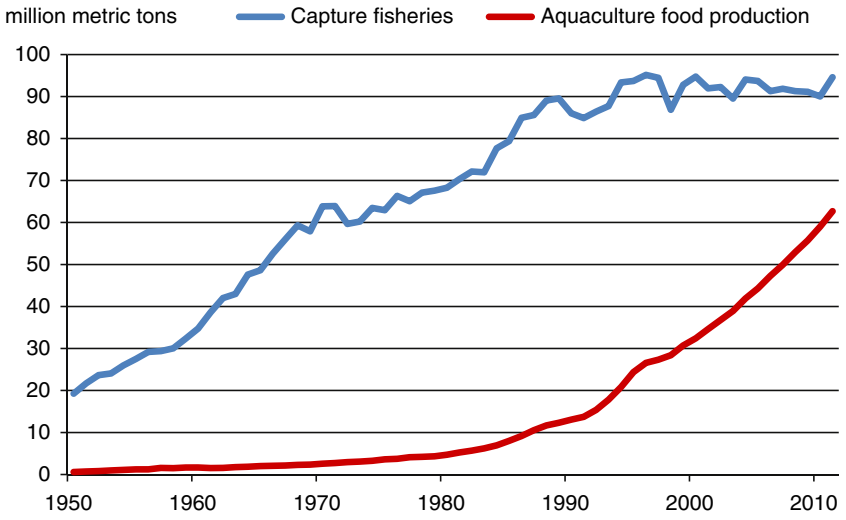

Figure 2 World capture fisheries and aquaculture food fish production during 1950–2011. Reproduced from FAO, 2013a. Aquaculture and Capture Production 1950–2011. Rome: Statistics and Information Service of the Fisheries and Aquaculture Department; FAO, 2013b. Cultured Aquatic Species Information Programme: *Pangasius hypophthalmus* (Sauvage, 1878). Available at: http://www.fao.org/fishery/culturedspecies/Pangasius_hypophthalmus/en (accessed 08.04.14); and FAO, 2013c. FAOSTATS. Available at: http://faostat.fao.org/site/291/default.aspx (accessed 08.04.14).

beef cattle is 12.7, which means that 12.7 kg of feed need to be used to produce 1 kg of beef (the animal, not only the meat). The FCR for poultry is much lower but still averages at 2.3 (Hall, 2011). On the contrary, the FCR for fish like salmon and carp is 1.3 and 1.5, respectively (Tacon *et al.*, 2011), making farming fish a more efficient business. In addition there are number of nonfed aquaculture commodities, such as mollusks, seaweed, and herbivorous fish, which provide valuable proteins and other micronutrients without depending on feed at all.

All this made the farming of fish increasingly needed and possible. There is also an inherent advantage of aquaculture, the number and diversity of species. There are hundreds of domesticated cattle breeds in the world, but all of these are usually classified into two major subspecies, zebu (*Bos indicus*) and European (*Bos taurus*) cattle, and they are believed to descend from the same species, *Bos primigenius* (Cunningham and Syrstad, 1987). However, 90% of aquaculture production is generated by 46 species of fish (FAO, 2013a–c). Although this poses considerable technological challenges, it also

provides opportunities to identify species and production systems that allow great efficiency for the given local conditions.

The production of pangasius (Vietnamese catfish) provides a nice example of the opportunities offered by aquaculture. Pangasius (*Pangasianodon hypophthalmus*), a species indigenous to Southeast Asia (Mekong River, the Chaopraya River and possibly the Mekong basins in Cambodia, Lao People's Democratic Republic, Thailand, and Vietnam, together with the Ayeyawady basin of Myanmar, see 'Relevant Websites' section), especially the Mekong region, used to be farmed in backyard ponds, traditionally cultured since the 1960s using wild-caught seed harvested from the Mekong River (Xuan and Hien, 2010). At that time pangasius was feeding the farmers who were growing it and the overall size of production was probably in the range of thousands of tons. It was not until the drop in cod harvests due to improper management of fisheries resources and the consequent moratorium issued in 1992 by the Canadian government to close cod fisheries (Hamilton *et al.*, 2004) that people started looking at farmed fish as a source of those beautiful white fillets that European and North American consumers cherish so much. The demand for white fillet boosted the production of pangasius, which from backyard ponds 'jumped' to commercial aquaculture operations, with an annual production over the past few years of more than 1 million metric tons from an area estimated to be 6000 ha in 2007 (Xuan and Hien, 2010). This means an average production of 200 ton ha^{-1} $year^{-1}$ (production of 2007 was 1.3 million metric tons), although production of 400–500 ton ha^{-1} have also been common (FAO, 2013a–c).

Seafood is generally thought of as 'food produced in the sea.' However, the industry moved forward with the concept of 'sea' food into considering seafood not only as the wild catches harvested from the seas, and all aquaculture production, but also including freshwater organisms (Wikipedia, 2013). As a matter of fact, although marine farming is responsible for 46.9% of the aquaculture production, 46.6% of farmed fish is generated from inland freshwater environments (FAO, 2013a–c). The remaining 6.6% of aquaculture is produced in brackish water environments, which are environments that lay in coastal areas where freshwater and the sea meet. The large marine production is primarily due to the inclusion in statistics of seaweed and other aquatic plants. When removing aquatic plants from the calculation, as seaweed is often used for uses other than food, the statistics look quite different. In fact 62.1% of the aquatic animals are produced in freshwater, with brackish water and marine environments accounting for 7.8% and 30.2% of the production, respectively (FAO, 2013a–c).

But where are all those rivers and lakes that make the production of 39 million metric tons of freshwater fish possible? Geographically speaking, if the aquaculture could be summarized in a single word, the word would be 'Asia.'

Table 1 Annual average rate of growth for food production between 1961 and 2011

	Cattle	*Poultry*	*Aquaculture*
Production in 1961 (million metric tons)	27.69	8.95	1.52
Production in 2011 (million metric tons)	62.54	101.74	62.70
Annual average rate of growth	1.64%	4.98%	7.72%

In: Subasinghe, R.P., Arthur, J.R., Bartley, D.M., *et al.* (Eds.), Farming the Waters for People and Food. Proceedings of the Global Conference on Aquaculture 2010, Phuket, Thailand, 22–25 September 2010, pp. 337–383. Rome: FAO and Bangkok: NACA.

Asian Aquaculture: The Champion

Nine out of ten of every kilogram of aquaculture products is produced in Asia (FAO, 2013a–c). A comparison of the production of aquaculture by continents dwarfs the continents like the Americas and Europe, where most of the salmon and trout, for many the emblems of aquaculture, are produced, which is quite obvious as the Americas and Europe account for only 3.5% and 3.2% of the global aquaculture production, respectively (Table 4).

Within Asia, two-thirds of the production comes from China, although other Asian countries such as India, Indonesia, Vietnam, or the Philippines are also major players. As a matter of fact the first non-Asian country to appear on national production statistics is Norway, which takes the eighth position due to its huge production of Atlantic salmon (Table 5).

Table 3 Protein content of major animal foods and feed conversion efficiencies for their production

Commodity	*Milk*	*Carp*	*Eggs*	*Chicken*	*Pork*	*Beef*
Feed conversion (kg of feed/kg live weight)	0.7	1.5	3.8	2.3	5.9	12.7
Feed conversion (kg of feed/kg edible weight)	0.7	2.3	4.2	4.2	10.7	31.7
Protein content (% of edible weight)	3.5	18	13	20	14	15
Protein conversion efficiency (%)	40	30	30	25	13	5

Source: Reproduced from Hall, S.J., Delaporte, A., Phillips, M.J., 2011. Blue Frontiers: Managing the Environmental Costs of Aquaculture. Penang, Malaysia: The WorldFish Center.

Again, just to put things in context, the production of countries like Vietnam and the Philippines, which take the fourth and fifth position in the national production statistics with a production of 3.1 and 2.6 million metric tons, respectively, is comparable to the production of continents like the Americas and Europe, which produce 3 and 2.7 million metric tons, respectively.

Economics of Asian Aquaculture

Aquaculture generated 107 billion USD in Asia in 2011, and many commodities were exported and consumed in other countries. Compared with national gross domestic product (GDP), the contribution of the aquaculture sector is not so significant, but it provides an important source of employment. Table 6 summarizes estimated number of fish farmer in 2010. It was estimated that approximately 16.6 million people were engaged in aquaculture and were concentrated in Asia (97%) (FAO, 2012). In addition, the sector provides numerous jobs in secondary activities, such as processing, packaging, marketing, and distribution. It is estimated that for each person directly engaged in aquaculture production, approximately three to four related jobs are generated in secondary activities (FAO, 2012), making the people directly or indirectly involved in the sector globally comparable with the population of some of the most populated European countries.

both production volume and value. In terms of production, there are 6 species of seaweed and 3 species of mollusks in the top 20 aquaculture species in Asia. However, in terms of value, Crustaceans (e.g., shrimp) are high in the ranking and whiteleg shrimp takes the first position; two other species are in top 10 positions as well (Tables 7 and 8).

Main Environments for Fish

In Asia, almost half of the production volume comes from freshwater (37 million metric tons, 48%), followed by marine environment (35 million metric tons, 46%) and relatively small production comes from brackish water (4 million metric

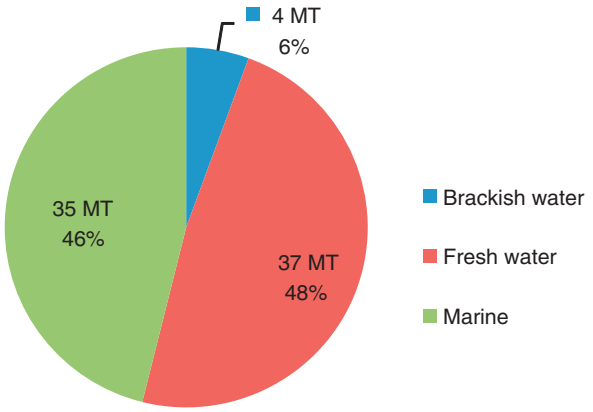

Figure 5 Asian aquaculture production by volume (million metric tons) in 2011.

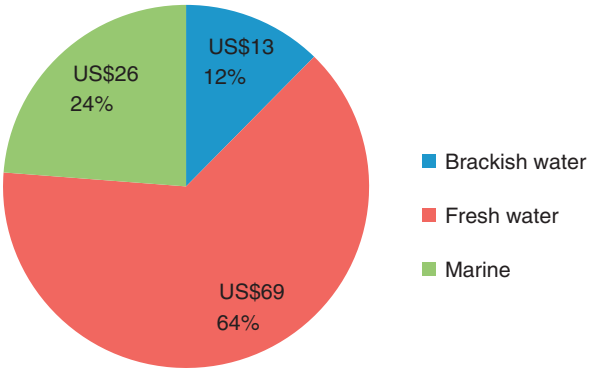

Figure 6 Asian aquaculture production by value (billion USD) in 2011.

tons, 6%). However, considering the value of the production, majority comes from freshwater (69 billion USD, 64%), followed by marine environment (26 billion USD, 24%) and brackish water (13 billion USD, 12%). These differences are shown in Figures 5 and 6 and are caused mainly by (1) large volume of seaweed and mollusks that are produced in marine environment but at relatively low values and (2) smaller quantity of high-value crustaceans produced in brackish water.

Sustainable Aquaculture Production

As described in earlier sections, aquaculture is conducted in various environments, such as inland water, brackish water, and marine environment, as well as being characterized by a large variety of culture species and farming system. This diversity offers both opportunities and challenges for sustainable aquaculture production. Considering the importance of the sector in providing quality nutrients (e.g., proteins and essential fatty acids), such sustainable growth is crucial from a nutritional and socioeconomic perspective and at the same time raises a number of environmental and social challenges.

The long-term development of sustainable fisheries and aquaculture sector is documented in the FAO Code of Conduct for Responsible Fisheries (CCRF) issued in 1995. Aquaculture development is particularly elaborated in Article 9 of this FAO CCRF document and contents are categorized in the following four areas: (1) Responsible development of aquaculture under national jurisdiction; (2) Responsible development within transboundary aquatic ecosystems; (3) Use of aquatic genetic resources; and (4) Responsible aquaculture at the production level (FAO, 1995).

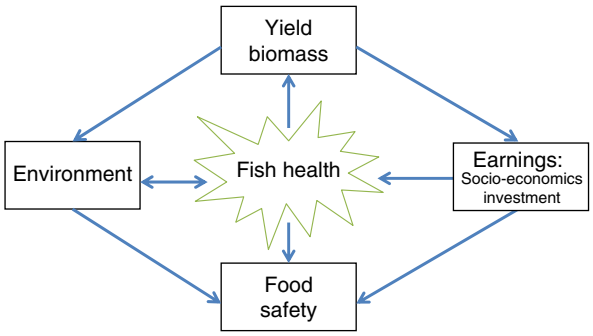
Inland waters are highly competitive resources for many sectors; moreover, demands on freshwater are expected to be doubled by 2050 due to increasing population. Of the estimated available 3800 km^3 of freshwater in the world, it is crucial to promote aquaculture and fisheries into currently dominating sectors, such as agriculture (70%), industries (20%), and domestic use (10%) (FAO, 2012). However, mariculture seems to offer great opportunities in terms of space availability. There are various mariculture cages that are operational in offshore environments; however, the economic viability of these farming system is one of the challenges for further expansion, particularly in Asia.

Regardless of the environment, there is also competition for resources that go into feed. Fed aquaculture productions (e.g., marine shrimps, marine finfishes, and eels) are largely dependent on capture fisheries for the supply of their major dietary source of protein and lipids. For example, on a global basis, it is estimated that the aquaculture sector consumed 3.72 million metric tons of fishmeal (60.8% of global fishmeal production) and 0.78 million metric tons of fish oil (73.8% of global fish oil production) in 2008 (Tacon *et al.*, 2011).

In 2012, FAO/APFIC/NACA Regional Consultation was held in Bangkok, which summarized key challenges to sustainable intensification of aquaculture in the Asia-Pacific region as follows (FAO/APFIC/NACA, 2012):

1. Genetics, improved varieties, and seed quality
2. Strengthen aquaculture biosecurity and health management
3. Availability, cost, and utilization of feeds and feed ingredients
4. Efficient or innovative use of land/water/energy
5. Reduction of environmental impacts of intensified aquaculture
6. Culture-based fisheries is an option to intensify production of open waters
7. Aquaculture as an attractive livelihood
8. Climate change and natural disasters
9. Markets

Although all of the above are issues to be addressed, arguably aquatic animal health management and the control of aquatic diseases is crucial.



Aquatic Animal Health Management

Aquaculture production systems are notorious for the variability in performance. It is not uncommon for survival in aquaculture operations to fluctuate between crops of several double-digit percentage points, sometime ranging from less than 10% to more than 50% and seldom reaching levels above 90% (authors' personal observation). Such variability offers both challenge and the opportunity for improvement.

Aquatic diseases are central to sustainability for a range of reasons:

- Diseases affect production, hence leading to economic losses for farmers.
- Diseases lead to the use of veterinary medicines, which is a global concern (WHO, 2006). In a context where, for example, crustaceans cannot be vaccinated and the number of commercially available vaccines for Asian finfish is extremely limited, this often leads to the use of antimicrobials, which can affect product quality. This loss of quality also affects prices.
- The use of antimicrobials and other products to reduce disease outbreaks, in addition to the release of pathogens, also affects the environment.
- The reduced earning implies a reduced capacity to invest in improved production practices, hence creating a vicious cycle.

This is exemplified in the figure below, which shows the central role of aquatic animal health management in the path toward aquaculture sustainability.

Asia has taken a proactive role in aquatic animal health management. In spite of the economic challenges associated with disease control in Asian aquaculture, the Fish Health Section of the Asian Fisheries Society has been organizing the Diseases in Asian Aquaculture since 1990. The Network of Aquaculture Centres in Asia-Pacific (NACA), a regional intergovernmental organization, manages the activities of the Asia Regional Advisory Group on Aquatic Animal Health, which, among others, updates regularly a list of diseases of importance to the region. Asia-Pacific countries use such list, which includes also diseases listed by the OIE, to report quarterly on their status with the objective of informing countries in the region on any potential threats while identifying capacity building needs.

Aquaculture Certification

When talking about sustainable development, it is almost impossible to neglect mentioning certification, which for many is synonymous with sustainability. At the earlier time, it is likely that most of the aquaculture production would have been used for local consumption; hence, aquaculture operations were small in nature. However, in the last couple of decades, commercial aquaculture started to flourish, with an increasing amount of fish being produced in larger scale operations and also being traded far and wide. In this regard, food safety standards were issued and international trade regulations were tightened. In addition to this basic requirement for trade, there are environmental and consumer concerns on aquaculture production, which resulted in increasing interest in the certification of aquaculture productions systems, practices, processes, and products from aquaculture. Nowadays, large number of public as well as private aquaculture certification schemes are being developed and implemented at international and country levels.

Although aquaculture certification could potentially serve as a mechanism to shift whole aquaculture industry to more sustainable direction, the implementation of these various schemes has been gradual and a number of issues have risen particularly related to technical barriers to trade for small-scale aquaculture producers. For example, some certification schemes have resulted in higher costs for producers without delivering significant price benefits to small-scale producer. In response to its member countries' requests to address such concerns, the FAO has recently released the technical guidelines on aquaculture certification to provide level playing field for development and implementation of robust and transparent certification schemes (FAO, 2011).

In 2013, the Best Aquaculture Practice (BAP) and the Aquaculture Stewardship Council (ASC) programs, which together with GlobalGAP are arguably the most important aquaculture certification schemes globally, counted a total of 312 and 65 certified farms, respectively, the greatest majority of which was in Asia (Table 9).

Table 9 Number of aquaculture-certified farms

Species	*Total*	*Asia*
ASC certified		
Pangasius	36	36
Tilapi	27	20
Salmon	2	0
Total	65	56
BAP certified		
Salmon	131	0
Shrimp	111	103
Tilapia	49	43
Pangasius	10	10
Mussels	8	0
Catfish	2	0
Jade Perch	1	1
Total	312	157

Abbreviations: ASC, Aquaculture Stewardship Council; BAP, Best Aquaculture Practice.

Future Forecast and Some Final Remarks

Aquaculture is here to stay and is likely to play an increasingly important role in feeding the future generations. FAO Fisheries and Aquaculture Department conducted the future forecast for fish supply and demand up to 2030. The assumptions made to

Table 10 Fish supply – demand projection for 2030

	Estimated supply 2030 (million metric tons)	*Estimated demand 2030 (million metric tons)*	*Supply–demand gap 2030 (million metric tons)*
Africa	11.7	18.7	– 7.0
Asia	156.5	186.3	– 29.8
Europe	18.6	23.4	– 4.8
Latin America and the Caribbean	16.2	18.3	– 2.1
Northern America	6.2	12.9	– 6.6
Oceania	1.5	1.8	– 0.3
World	210.7	261.2	– 50.6

Source: Reproduced from FAO Statistics and Information Service of the Fisheries and Aquaculture Department, 2013. Aquaculture and Capture Production 1950–2011. Rome: Food and Agriculture Organization of the United Nations.

conduct this future forecast were (1) aquaculture follows recent trends and capture fisheries remain stationary and (2) consumers' consumption preference and fish prices unchanged to calculate per capita fish demand using International Monetary Fund (IMF) GDP projection and multiply it by the UN population projection.

The results indicated that there will be 51 million metric tons of fish shortage in the world with most severe insufficiency in Asia, amounting to almost 30 million metric tons (Table 10).

This production increase needs to be driven by expansion of sustainable aquaculture, which can be achieved only through efficient farming systems that operate in harmony with environment while providing social benefits. Asia is both the top producer and top consumer of aquaculture products, which is likely to change for decades to come. For the livelihood and safety of Asian people it is essential that the sustainability challenges of the sector are addressed in a timely manner. This requires a concerted effort that brings together both the public and the private sectors. The experiences from pangasius aquaculture in Vietnam have shown that public–private cooperation can achieve an unprecedented shift toward increased sustainability, with a current production of ASC-certified pangasius of more than 20%, which was achieved within approximately 2 years thanks to a partnership between the Vietnamese government, producers, buyers, and nonprofit organizations (authors' personal observation). Public–Private Partnerships are increasingly becoming key instruments to achieve similar sustainability shifts and, with a growing competition for resources, are likely to become essential for the aquaculture of the future.

GUIDE TO USING THE ENCYCLOPEDIA

Structure of the Encyclopedia

The material in the encyclopedia is arranged as a series of articles in alphabetical order.

There are four features to help you easily find the topic you're interested in: an alphabetical contents list, cross-references to other relevant articles within each article, and a full subject index.

1 Alphabetical Contents List

The alphabetical contents list, which appears at the front of each volume, lists the entries in the order that they appear in the encyclopedia. It includes both the volume number and the page number of each entry.

2 Cross-References

Most of the entries in the encyclopedia have been cross-referenced. The cross-references, which appear at the end of an entry as a See also list, serve four different functions:

i. To draw the reader's attention to related material in other entries.
ii. To indicate material that broadens and extends the scope of the article.
iii. To indicate material that covers a topic in more depth.
iv. To direct readers to other articles by the same author(s).

Example

The following list of cross-references appears at the end of the entry Critical Tracking Events Approach to Food Traceability.

> *See also*: Agribusiness Organization and Management. Food Chain: Farm to Market. Food Labeling. Food Law. Food Packaging. Food Security: Development Strategies. Food Security: Food Defense and Biosecurity. Food Security, Market Processes, and the Role of Government Policy. Food Security: Postharvest Losses. Global Food Supply Chains. Government Agricultural Policy, United States. Regulatory Conventions and Institutions that Govern Global Agricultural Trade

3 Index

The index includes page numbers for quick reference to the information you're looking for. The index entries differentiate between references to a whole entry, a part of an entry, and a table or figure.

4 Contributors

At the start of each volume there is list of the authors who contributed to that volume.

SUBJECT CLASSIFICATION

Agriculture and People

Agribusiness Organization and Management
Agricultural Cooperatives
Agricultural Ethics and Social Justice

PREFACE

Food is absolutely necessary for human existence, yet for most in wealthy nations it is largely taken for granted because of its abundance. Sufficient food is a concern, however, for about 1 billion of the earth's inhabitants today who often go to bed hungry. Food security in a broad sense is becoming a worry of the future for those who understand the limitations of our earth's ecosystems. Malthusian prophecies have so far been wrong, but there is growing concern that we are rapidly reaching the point where feeding the world's growing and richer population will be at the cost to our environment that is unacceptable. In the next few decades we face the challenge of growing more food, with less water, with less fertilizer on less land – because of the growth of urban areas on prime agriculture land. We also face the largely unknown consequences that global warming will have on agricultural production. During the last century agricultural scientists were able to bring cutting-edge science into traditional agricultural practices and increase food production sufficiently to prevent global food shortages. The hope that new scientific discoveries will provide the means to keep ahead of world food demand is complicated by a growing public discomfort with biotechnology being applied to food production.

The concept of services being provided by the ecosystems of the earth is a fairly recent attempt to understand and place value on functions of natural lands that have historically been assumed to have few limits. In the past, if more food was needed, new lands were converted from forests or steppe lands into farm land and new water systems developed to provide the water needed for agriculture. When human populations were low our activities were largely buffered by the abundance of forest and steppe, but too late, we are beginning to understand that these provisioning services of our ecosystems are being overused and are no longer buffered by the abundance of wild lands and waters. We are rapidly losing our planet's biodiversity, irreplaceable ground water is being unsustainably consumed, and major river systems are being overused and polluted. Our oceans, the last place on the planet that still support our hunter and gathering traditions may not be able to sustain these activities into the future. And, food production and processing activities contribute to the greenhouse gas emissions that are rapidly warming our planet. Agriculture is the single greatest user of the earth's land and water resources. In the concept of ecosystem services, provisioning or providing food for all organisms is one of the services provided by ecosystems. Human population growth has and will continue to overtax the ecosystems we inhabit. The ultimate outcome of this major diversion of nature's resources into provisioning the human species is unknown, but it is critically important for us to understand what we must do to sustain our planet.

The breakthrough discovery about 10 000 years ago that plants and animals could be bred to provide a more abundant and secure food source was the foundation upon which all other human activities were able to flourish. Activities other than finding food now became possible and our diverse cultures were able to develop because of agriculture. Until fairly recently, however, the majority of the population of most nations was still directly involved in producing food. Mechanization of agriculture and continued improvements in genetics, fertilizers, and pesticides made food production very efficient in developed nations. In the United States, the leading nation in value of agricultural exports, less than 2% of the workforce is currently employed in producing food. The United States, however, is alone among the most populous nations of the world in having such a small population employed as farmers. In countries such as China, India, Indonesia, and Nigeria the majority of people are rural and involved in agriculture either directly or indirectly. But, as food production becomes more efficient in these countries, and as wages increase in other sectors, a major shift is occurring from rural to urban occupations. This revolution is potentially as important in affecting our cultures and community structures as was the development of agriculture. Many nations are currently experiencing a very rapid transition from rural to urban living with all of the social and logistic problems associated with such rapid structural changes. While this transition in our social and cultural structures is a broad subject, it does have significant impacts on agriculture and our food systems. To mention just a few, agriculture labor, food transport, food safety, and access to healthy food.

There is genuine concern among agricultural scientists that human populations and changing diets are outpacing our ability to meet the increasing food needs of the planet. In the first iteration by Academic Press in 1994 of the *Encyclopedia of Agricultural Science*, Noble Prize Winner Normal Borlaug wrote in its forward:

> Had the world's 1990 food production been distributed evenly, it would have provided an adequate diet (2350 calories, principally from grains) for 6.2 billion people – nearly one billion more than the actual population. However, had the people in Third World countries attempted to obtain 30% of their calories from animal products – as in the United States, Canada, or European Economic Community countries – a world population of only 2.5 billion people could have been sustained – less than half of the present world population.

The issue raised by Dr. Borlaug is probably the most important challenge we face. Human behavior and the food choices of consumers will determine the outcome of the race between food supply and population. Population control has been advocated for decades, and in some cases has become part of national policy, but the world's population continues to grow. Science breakthroughs cannot solve our food security and environmental quality challenges if consumers reject food that is not traditionally produced. Likewise, if meat products and other inefficiently produced food continue to be in high demand by consumers, there will be increased pressure on our food production systems. As supplies become short, prices rise. While this may be good for farmers, high food prices and food shortages will probably undermine our efforts to preserve the

world's remaining arable land as natural lands. We must change human behavior to solve the problems we face.

Food choices, nutrition, diets, food cultures, water and air quality, GMOs, global warming, food security, and similar topics are daily in the news throughout the world. We are all concerned about these issues, yet with all of the information easily available in the popular media about food there seems to be too little informed discussion on these various topics. In planning the *Encyclopedia of Agriculture and Food Systems* the editorial committee chose to organize the topics primarily by issues, rather than to focus on a traditional topic approach. We organized the issues that would be discussed in the chapters around the broad topics of Agriculture and People, Agriculture and the Environment, Agricultural Products, Plant Health Management, Animal Health Management, and Agriculture and Science. The issues raised in this preface are the ones that we felt needed to be addressed in this encyclopedia.

The associate editors joined me in the development of topics for the encyclopedia and were responsible for working with the authors – they deserve particular recognition. I was fortunate to be joined by a very distinguished group of colleagues who, I hope, are still friends. They spent much more time and effort in bringing this project to completion than any of us anticipated. I want to thank our authors who while overly committed and overworked, fulfilled their commitments to contribute to this work. I have been impressed with the quality of their contributions. The editorial staff of Elsevier have had the professionalism and patience to work with scientists who do not work under the same time and budget constraints that the staff work. I want to particularly thank Kristi Gomez, Donna de Weerd-Wilson, and Simon Holt who, each in succession, oversaw this effort, and I especially thank the project managers, who worked directly with me, and the associate editors, Kate Miklaszewka-Gorczyca, Will Bowden-Green, and Sam Mahfoudh.

This article is a summary of Beef Cattle Production Systems by Andy Herring © CAB International 2014, and reproduced with permission from CAB International, Wallingford.

Glossary

Beef The meat from cattle carcasses.
Bos indicus Distinct subspecies of cattle that are descendants of domestication in South Central Asia (India); these cattle generally have a hump over the shoulder and are known for extreme tropical adaptation.
Bos taurus Distinct subspecies of cattle that are descendants of domestication in the Near/Middle East and comprise the historical breeds of Europe; these cattle are nonhumped.
Bull An intact (uncastrated) male bovine.
Calf A young bovine, generally less than 12 months of age.
Cow A female bovine that has reproduced. The word cow is not a general descriptor of cattle.
Criollo A group of cattle that trace origins to Spain and Portugal and are known for tropical adaptation, especially in South America.
Heifer A female bovine that has not yet reproduced, or just recently has given birth to her first calf.
Sanga A group of cattle native to Eastern and Southern Africa that have a neck hump and are known for tropical adaptation.
Steer A male bovine that has been castrated before reaching puberty.

Beef Cattle Operations and Production Systems

In the broadest sense, cattle producers can be classified as cow-calf, stocker/grower, or finisher producer (Table 1). Some operations may comprise combinations of these. At the cow-calf level, operations (or herds) are seedstock or commercial. The systems concept of beef production (production philosophy that includes considerations of potential genetic–environment–market interactions (see BIF, 2010)) presents challenges both to seedstock producers (producers of predominantly purebred breeding animals) and to commercial cow-calf producers (those that produce market beef animals) as well as to producers of growers and finishers. The more reliant the cattle producers are on 'natural' production environments, the more critical the understanding and utilization of systems-based approaches become.

Animals sold for breeding purpose have higher animal values (prices) than commercial animals. Many beef cattle breed societies or associations that record pedigree information and issue official certificates of registration exist. Utilization of registered purebred cattle for typical market uses is undesirable as they do not have higher value carcasses, may have less desirable growth or cost of gain compared with crossbred cattle, and have a higher animal initial cost. Growing and finishing phases may be stand-alone operations or may be additional components to a cow-calf operation as part of an overall production system. It may also be possible that some systems include ownership at least in part further into the supply chain, such as sales through butcher shops or through specific beef programs. The overall impact of various production systems have been evaluated by several groups regarding productivity and environmental impact.

A recent report (Gerber *et al.*, 2013) from the FAO has estimated potential livestock contribution to climate change. This report has stated that 14.5% of the human-induced global greenhouse gas emissions are attributed to farm animals. This report further stated that meat and milk production from cattle accounted for 41% and 20%, respectively, of farm animal contributions and that pig meat and poultry (meat and eggs) contributed 9% and 8%, respectively. Table 2 shows the estimated emissions from global dairy and cattle meat production.

There is a high degree of variability for both total emissions and categories of emissions across geographical region and production system in both milk and beef production. It may not be obvious why dairy systems are being discussed in a beef production article, but there are many areas of the world where the vast majority of beef production comes as a by-product of milk production systems. The regions of the world Gerber *et al.* (2013) identified as being the lowest for greenhouse emissions from beef production were North America, Europe, the

Table 1 Types of beef cattle production systems

Name	*Description*
Seedstock	Seedstock herds are mainly purebred herds with animals registered in breed society herd books that produce animals for breeding purposes. They can be classified as elite and multiplier operations. Elite operations produce the highest valued breeding animals in the breed and sell animals to other seedstock operators; multiplier operations sell primarily bulls to commercial cow-calf operations
Cow-calf, production of weaner calves	Cow-calf operations are driven by cow reproductive performance and overall productivity evaluated through calf production to weaning. Commercial cow-calf operations may sell calves close to weaning or may also/instead sell animals from grower and finishing phases. Different combinations of traits will receive emphasis relative to what age/stage of development animals are sold
Stocker, grower, and developer	These operations purchase or obtain young animals for growth. This can be grazing based on rangeland, forage crops, row crop residues, or may be feedlot based. Cattle are grown for some time, but not to completion of market size, weight, or fatness. These may utilize calves destined for beef, or replacement heifers or males for breeding purposes
Finisher	These operations produce cattle that go directly to slaughter. These can be grazing entirely, grain-assisted with grazing, confined feeding of green crops (such as cut-and-carry), or confined feeding of high-grain/concentrate diets. These operations can obtain cattle from cow–calf operations or from grower operations
Combination seedstock and commercial	A commercial herd as component of a seedstock operation adds flexibility for progeny testing, production of recipient females for embryo transfer; it is common that some seedstock operations also have a commercial herd rather than a primarily commercial herd developing a seedstock portion

Table 2 Estimated global production, emissions, and emission intensity from cattle milk and meat production

System	*Production (million tons)*		*Emissions (million tons CO_2 eqivalent)*		*Emission intensity (kg CO_2 eqivalent per kg product)*	
	Milk	*Meat*	*Milk*	*Meat*	*Milk*	*Meat*
Dairy	508.6	26.8	1331.1	486.2	2.6	18.2
Beef	–	34.6	–	2338.4	–	67.6

Russian Federation, the Near East and Northern Africa, and Oceania (Australia and New Zealand). Other areas that were identified with highest greenhouse emissions rely mostly on grass-finishing production of beef and produce animals for harvest at later relative ages. An encouraging recommendation from this report was that management techniques that increase efficiency of production (such as increased digestibility of feeds, improved animal husbandry, etc.) also appear to reduce carbon footprints. In most instances the optimal production practices that increase efficiency can also increase profitability for beef cattle producers.

Successful beef cattle management relies on knowledge of many disciplines, such as breeding and genetics, nutrition, reproductive physiology, health, behavior, and meat science as well as marketing options and market expectations. However, it cannot be overemphasized that familiarity with beef cattle from regular live animal evaluation is crucial for success in all of these discipline areas and provides important insight into meeting most production goals. Figure 1 illustrates some general physical areas that are important to evaluate in beef cattle.

Breeding and Genetics

Discussion of cattle breeding and genetics begins with their classification into evolutionary groups (Table 3). Animals of the genus *Bos* are known as the true cattle and include yak, banteng, gaur, kouprey, and domesticated cattle. Yak, banteng, and gaur have domesticated populations as well as wild populations. The autosomes of cattle (*Bos* spp.) are acrocentric and the X chromosome is submetacentric; however, in *Bos taurus* the Y chromosome is submetacentric, whereas in *Bos indicus* it is acrocentric.

Domesticated cattle (*B. taurus* and *B. indicus*) were developed from the ancient wild ox (aurochs, aurochsen plural, and *Bos primigenius*) that existed from the European (present-day Britain) Atlantic coasts to the Asian Pacific coasts. Several cave paintings in Western Europe show artists interpretations of the appearance of these animals. They had long horns, were lean, apparently light muscled in hindquarters, and had medium-length hair with large skeletal size, perhaps 2 m (6 ft) tall at the shoulder (Porter, 1991). *Bos indicus* and *B. taurus* are believed to have arisen from two distinct domestication events, and the common ancestors of these two groups may have separated 100 000 years ago or more (well before domestication).

Breeds

There are approximately 1000 different breeds of cattle globally. Most breeds have been developed purposely or have evolved from local cattle types. In the past 100 years, several

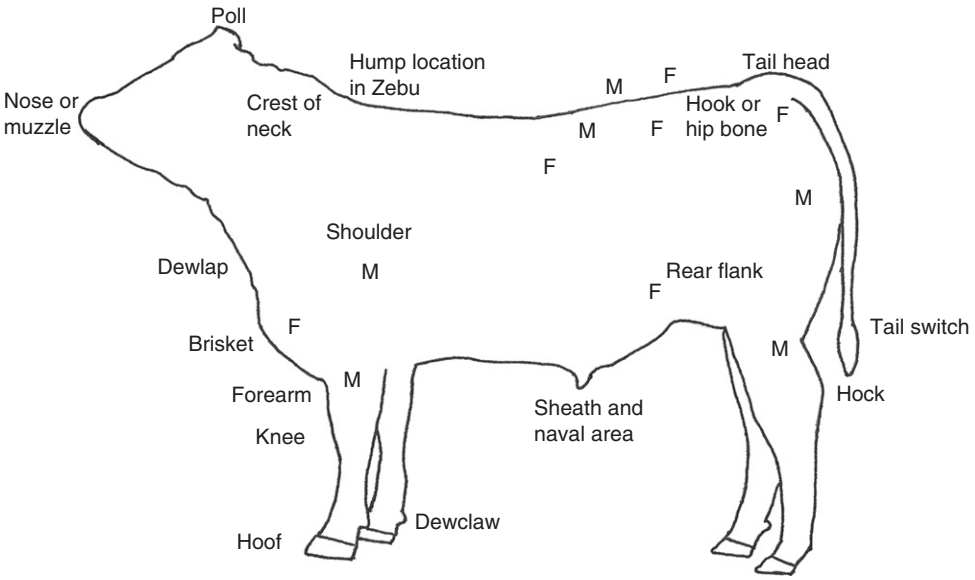

Figure 1 Identification of some general beef cattle body areas and locations to evaluate fat (F) and muscle (M).

Table 3 Classification groups of cattle

Name	*Description*
Class – Mammalia	Have hair and mammary glands that secrete milk
Subclass – Theria	Marsupials and placental animals with nipples on mammary glands
Infraclass – Eutheria	Fetus develops entirely by means of placenta
Order – Cetartiodactyla	Even-toed ungulates (grazing animals) and whales
Suborder – Ruminatia	Stomach with three or four chambers and no upper incisors
Infraorder – Pecora	Stomach with four chambers, the true ruminants
Family – Bovidae	Hollow horned; in general cattle-, antelope-, and goat-like species
Subfamily – Bovinae	Cattle, spiral-horned antelope, and nilgai
Tribe – Bovini	Bison, buffalo, and cattle
Genus – *Bos*	Yak, gaur, banteng, kouprey, and domesticated cattle
Species – *Bos indicus* or *Bos taurus*, or hybrids	Domesticated cattle arose from the ancient Aurochs (*Bos primigenius*) in two separate events

'new' breeds have been developed by crossing two or more existing breeds into what has been called a composite breed, but this is not a new phenomenon.

Breeds within a biological type share many similar production characteristics, and the proper choice of biological type or types should be the genetic basis for a beef cattle production system. If a breed type is used in a production environment that does not suit it, the input costs will be very high in order to obtain a desired level of production or the level of production will be quite disappointing relative to the lower level of inputs. The concept that breeds (or biological types) do not have consistent performance advantages (or disadvantages) across all environments is referred to as genotype × environment interaction. There is obviously no single breed of cattle that is superior for all traits of importance across all production environments.

Not all of the terms used in Table 4 to describe cattle groups are exclusive of others. In fact, combinations of these terms may many times provide the most useful descriptions for several breeds or types, such as *Bos indicus* dairy, British beef, criollo dual purpose, etc. Many breeds have been taken from their area of origin and been further developed or changed for local conditions. Further, the same breed at an earlier point in time may not be the same type of animal later, particularly if the group is responding to some form of selection (natural or artificial) (Table 5).

Genetic Improvement Strategies

The ability to genetically alter traits is a function of the degree of genetic influence on those traits. The term heritability (historically denoted by h^2) describes the percentage of the phenotype differences that are attributed to breeding value (gene content) differences. This is an important concept because the h^2 value is directly related to how quickly a trait may be changed due to selection, and the value can vary substantially across traits. Table 6 shows the heritability values for several traits important for beef cattle production (Figure 2).

Many people may assume that if the heritability of a trait is low then there is little genetic influence; however, this is typically not the case. Heritability is a function of the individual genes or alleles that affect traits without regard to their potential interactions. Many traits are affected by interactions

Table 4 General classifications and descriptions of some fundamental biological types of domesticated cattle that relate to production and adaptation aspects

Term	*Description and background*
Subspecies	
Bos taurus	Nonhumped breeds of the world, originally from the Middle East
Bos indicus	Shoulder-humped breeds of the world, also known as zebu (cebu) originally from Indian subcontinent of Asia and generally viewed as highly tropically adapted
Purpose	
Beef	Cattle produced for the primary purpose of meat production
Dairy	Cattle produced for the primary purpose of milk production
Draft	Cattle used primarily for farm-related work and transportation
Dual purpose	Cattle intended for two major purposes, such as milk and beef, milk and work, etc.
All purpose	Cattle used for all (general use) purposes as historically with subsistence agriculture
Geography	
British	Breeds from British Islands off European continent developed for meat production
Caucasian	Short-horned ancient-type of *B. taurus* cattle from Mediterranean, the Middle East, Eastern and Southeastern Europe, and Northern Africa
Chinese yellow cattle	Indigenous domestic cattle of China, not a reference to coat color. Common yellow cattle are typically nonhumped; yellow cattle further south have some evidence of a hump
Continental European	Breeds from Western and Central Europe used for meat production, but many had ancestors also used for draft; several are dual purpose meat and milk
Criollo	Tropically adapted *B. taurus* cattle of North and South America whose ancestors originally came from the Iberian peninsula of Spain and Portugal
Gray Steppe	Long-horned, light haired, and dark-pigmented *B. taurus* cattle of Eastern Europe considered an ancient type
Podolian	Breeds of Central Europe, primarily Italy, which were derived from eastern steppe cattle origin and include Apulian, Chianina, Maremmana, Marchigiana, Piedmontese, and Romagnola
Sanga	Cattle native to Africa that possess a neck hump, originally in Eastern and Southern African continent, some have classified Sanga as *B. taurus* because these breed possess a submetacentric Y chromosome
Western African humpless	Nonhumped breeds that are indigenous and survive in the tsetse fly region of West Africa and include Baoulé, N'Dama, Kuri, and Lobi
Japan/Korea	Wagyu/Hanwoo East Asian breeds known for extremely high levels of intramuscular fat deposition ability

of genes/alleles (such as when an allele is dominant over another or when the genotypes at different spots of the genome interact to influence the phenotypic expression). These potential nonadditive genetic interactions typically influence many traits through the phenomenon of heterosis (hybrid vigor). This phenomenon occurs when the crosses of parental stocks perform more favorably than expected, which is based simply on the amount of parental stock in the crossbred animals. Table 7 provides general guidelines of heterosis expectations relative to heritability for types of traits in beef cattle. Consideration of both of these genetic influences is quite important for beef cattle production systems but can have varying relative importance in specific production components. In the vast majority of situations, some type of crossbreeding system where crossbred cows are utilized allows improved productivity when production of market beef animals is the goal (Figure 3).

Nutrition

Beef cattle as ruminants have the ability to convert forage into meat production that cannot directly occur in nonruminant species. Consequently, cattle and other grazing livestock can commonly utilize lands that are not functional for other agricultural uses, such as farming. Depending on the geographical region, the ability to match the nutritional requirements of cattle to environmental resources is highly related to beef cattle productivity and profitability. More intensive beef cattle production systems will likely use more detailed nutritional information than total digestible nutrients (TDN) and crude protein (CP) in nutritional management; however, for general beef cow herd nutritional management these values present useful tools.

The nutritional requirements of cattle fluctuate with their phase of life cycle and stage of production. The general considerations associated with energy (represented by TDN) and protein (represented by CP) are provided in Tables 8 and 9. Both energy and protein in diets of cattle need to be adequate so that body condition score (estimate of percent body fat) is not too low, which will hinder reproduction and growth. Considerations of all important nutrients, including minerals, vitamins and water, are vital for optimal beef cattle management.

In grazing situations, supplemental nutrients may be offered to complement existing forage resources. Supplements may be minerals or vitamins or may be energy or protein. In other situations complete diets may be fed to cattle as with intensive production systems (Figure 4).

Feeding Cattle under Intensive or Confinement Conditions

In many situations cattle are fed a complete mixed diet (or may be called a total mixed ration), where everything they

Table 5 Examples of some breeds (excluding recent composites) with regard to biological groupings

British beef		*Sanga*	
Angus/Red Angus	Hereford	Africander (Afrikaner)	Mashona
Belted Galloway	Highland	Ankole	Nguni

Baladi	Greek Shorthorn	Kazakh	Qinchuan
Brown Atlas	Kurdi	Luxi	Tibetan
		Mongolian	Yanbian

[a]Some of these would be considered dual purpose or dairy type.
[b]Although the term criollo (or crioulo) generally refers to cattle developed in the New World from imported Spanish and Portuguese cattle, several breeds in present-day Spain and Portugal, such as Barrosã, Morucha, and Retinta, etc., would also be in this category.

consume is provided to them as in a feedlot. In some situations there may be conditions that warrant intensive feeding of cattle for a particular stage of production or environmental situation (such as drought, etc.). **Tables 10** and **11** provide some examples of diets to feed growing cattle. Adequate daily supply of clean water is crucial; cattle are expected to consume approximately 1 l of water per every 12 kg of live weight (1 gal per 100 lb) daily under nonextreme conditions.

The diets, mentioned in **Table 10**, which are appropriate for growing cattle can also be used for mature cows or feedlot fattening (finishing) of growing or older cattle. The rate of weight gain associated with any diet fed to cattle depends on their current weight (and stage of production) and the rate of intake of the diet. Usually, with intensive feeding of cattle there is a balance desired between increased production potential and increased costs. This same concept holds true for grazing situations but may not be obvious to managers if they do not know the forage cost or consumption. Any ration that is formulated to meet nutritional requirements must be fed at the recommended rate for it to be effective as it was designed.

Proper feeding of cattle is essentially proper feeding of the rumen microbes. Thus, it is obvious that rapid transitions from drastically different diets could cause digestive problems when the rumen microbial population has its nutrient inputs severely changed; hence, transition of cattle across drastically different diets needs to occur in incremental steps (**Figure 5**).

The ability to 'step up' cattle from a low-concentrate to a high-concentrate diet should be of concern to anyone providing feed to cattle, but it is of critical concern to feedlot managers and personnel. Feeding cattle much grain alters the rumen digestion processes and can lead to acidosis and potentially death but can also cause general digestive upset and bloat. Most feedlots utilize a 3–6 diet step-up plan that transitions cattle from low-concentrate, high-roughage diet to a high-concentrate, low-roughage diet for finishing, which avoids potential digestive problems. **Table 12** provides example of some feedlot diets with varying amounts of concentrate. There are both science and art needed in effective cattle feeding.

Manure Production

It is appropriate that the last topic discussed under nutritional concepts is manure production. The amount and nutritional composition of manure vary directly as a function of the diet according to digestibility and specific feedstuffs consumed. Manure is the waste produced from digestion and

Table 6 Heritability estimates for some traits in cattle

Trait	*Estimate*
Reproductive traits	
Age at first calving	0.10–0.25
Age at puberty	0.20–0.40
Calf survival	0.10
Calving interval	0.10

Fat (%)	0.51
Bone (%)	0.45

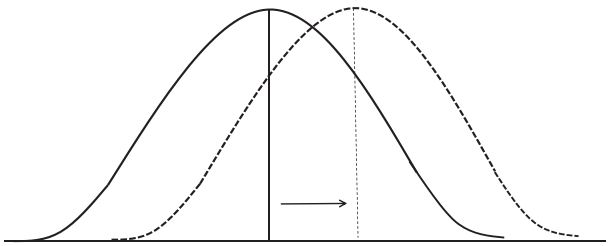

Figure 2 Concept of selection response. Selection response for a quantitatively inherited trait has implied shifting the mean of a population over time as a reflection of which animals are allowed to become parents.

is composed of both urine (the liquid waste removed from the blood by the kidneys) and feces (the semisolid waste that comes from the large intestine). The manure of cattle is composed of water, undigested feedstuffs, living and dead microbes, plant nutrients, and salts. Manure can be used to improve soil fertility but can also be a contaminant for water sources or can add excessive nutrients to soil or water sources. Manure management can be a formidable environmental issue for feedlots or other areas where cattle are intensively fed. Table 13 provides general guidelines that can be followed to predict manure production from different sizes of cattle.

Reproduction

Reproduction in beef cattle herds is the primary limitation for beef production systems, and the amount of beef that can be produced is a direct function of animal numbers. Some reproductive considerations specific to beef cattle are addressed here regarding female, male, and herd concepts.

Female Considerations

The estrous cycle in cattle is defined as the time between two consecutive estrus periods (time between heat periods) of a female. In cattle the estrous cycle is 21 days long on average. The length of the heat or estrus period itself is approximately 12–18 h, and ovulation typically occurs 24–30 h after the onset of estrus (beginning of heat period), so this typically corresponds to approximately 12 h after heat (and is the basis of the old recommendation that if a cow is in heat in the morning, breed it in the evening that day, and if it is in heat in the evening, breed it the following morning, otherwise known as the am–pm rule).

Heifers must reach puberty at an early enough age where herd fertility is not impeded, and this is critical when there are defined breeding and calving seasons. In many environments and with most *B. taurus* breeds and their crosses, age of puberty is not a limiting factor of reproductive success, provided that adequate nutrition is available. Puberty in heifers can be defined in different ways, such as time of first ovulation, time of first estrus, or time of first pregnancy carried to full term; here it means the time when a heifer can first become pregnant and produce a calf. Breeds that are known for high levels of milk production are known to have earlier age of puberty than breeds with lower milk production potential. Within the same level of milk production, breeds that are larger in size may reach puberty later than those of smaller mature size, but this relationship is less precise than with milk production.

Heifers of most *B. taurus* breeds reach puberty at 10–13 months of age when nutrition is not limiting; however, in many dual-purpose breeds this can be as low as 6 months or even earlier. In those cases puberty may be so early that some of the bull calves may breed some of their heifer mates before they are weaned, which presents other reproductive management challenges. This is the exception rather than the rule in most situations. In many environments, a target calving age of approximately 24 months is realistic with *B. taurus* breeds and most *B. indicus–B. taurus* crosses. With limited feed resources, a more realistic age of first calving is approximately 36 months

Table 7 Summary of heritability and heterosis levels for beef cattle production traits

Type of trait	*Heritability*	*Heterosis*
Female fertility and calf survivability	Low	High
Male fertility, growth, early life body size, and intramuscular fat (i.e., marbling)	Moderate	Moderate
Product-type traits, loin eye area, fat depth, mature size, and linear body measurements	High	Low

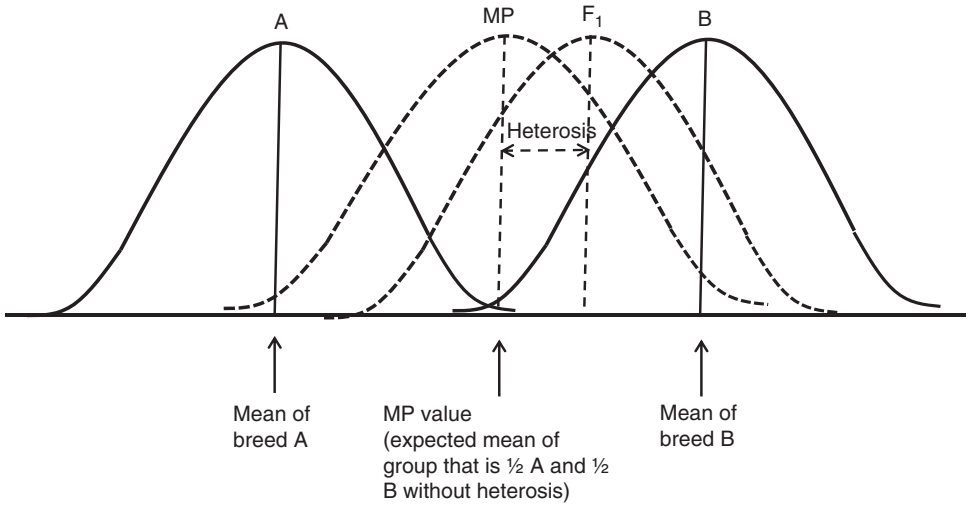

Figure 3 When crossing two breeds (A and B), the mid-parent(MP) value is halfway between the purebred means. The amount of deviation of the crossbred population mean from the MP value is the amount of heterosis. F_1 – Refers to the first cross progeny resulting from mating purebred parents of different breeds such as A sires with B dams, and, B sires with A dams.

Table 8 General guidelines for total digestible nutrients (TDN) and crude protein (CP) requirements for cattle

Class of cattle	*TDN (%)*	*CP (%)*
Growing animals	60–65	12–13
Lactating mature cows	55–60	10
Dry mature cows	50–55	7–8

Table 9 Production cycle/calendar of the cow herd thought of in 3-month increments relative to energy and protein requirements

Stage	*Total digestible nutrients (%)*	*Crude protein (%)*
Early lactation	Highest	Highest
Mid-lactation–early pregnancy	Intermediate	Intermediate
Late lactation–mid-gestation	Lowest	Lowest
Late gestation	Intermediate	Intermediate

because the heifers may be of 18–24 months before they reach puberty. Increase in nutritional plane and percent body fat reduces age of puberty in all breeds and crosses, and heterosis exist for age of puberty and will cause crossbred heifers to start cycling before the purebred average. The first estrus (heat) period may not have as high chance of conception as other estrus periods, so ideally heifers would have multiple estrous cycles before they have to get bred.

Weight management is important from the time heifers are born until the time they leave the herd as cows. It is important to have a good idea of what the mature size and weight of heifers will be because it is recommended that 50–60% of the mature weight at body condition score of 5 (moderate fat cover on a 1–9 scale, approximately 5 mm of fat cover over last two ribs, and approximately 18–20% body fat) is the target breeding weight for heifers, and 85–90% of their mature weight is the recommended target calving weight. Both of these targets ensure that heifers will be in the proper body condition at these critical production time points. Cows that can maintain body condition score close to 5 following calving have the highest chances of breeding back annually (Figure 6).

Artificial Insemination

Artificial insemination (AI) is a reproductive tool that can greatly aid in breeding programs and is widely available for beef cattle producers. Semen is commonly collected on highly prized bulls and available for purchase. In general, bulls are kept at facilities specialized in semen collection and processing. The semen is collected by means of an artificial vagina when the bull mounts a fixed 'dummy' structure or another animal. After collection, the semen is evaluated for its quality (abnormalities, motility, etc.), has some type of extender solution added to it, and is placed into plastic straws that are labeled with the facility code, breed, and individual ID of the bull. The straws are then

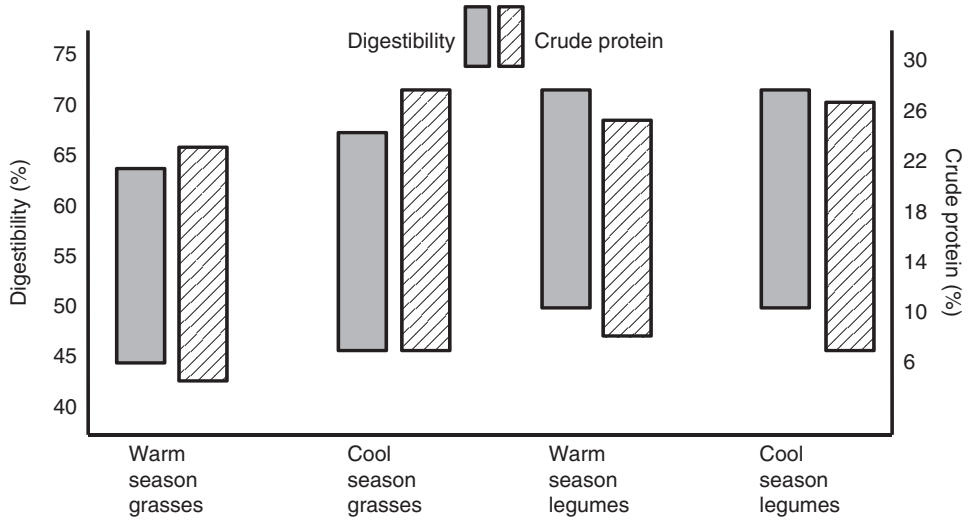

Figure 4 General guidelines for energy (digestibility as TDN) and CP content of different classes of forage for meeting cattle nutritional requirements. All forage species are highly variable within and across time and location. Annuals may be slightly higher in digestibility than perennials.

Table 10 Example of growing diets than can be fed to weaned cattle

Example 1	*Proportion (%)*	*Example 4*	*Proportion (%)*
Sudan hay	55.7	Grass hay	54.7
Wheat	20.0	Wheat	20.0
Maize	18.0	Grain sorghum	19.0
Soybean meal	5.0	Soybean meal	5.5
Dicalcium phosphate	0.5	Dicalcium phosphate	0.5
Limestone	0.5	Limestone	0.5
Salt	0.3	Salt	0.3
Example 2	*Proportion (%)*	*Example 5*	*Proportion (%)*
Grass hay	52.2	Sudan hay	57.2
Grain sorghum	40.0	Maize	35.0
Soybean meal	7.0	Soybean meal	7.0
Dicalcium phosphate	0.5	Dicalcium phosphate	0.5
Limestone	0.5	Limestone	0.5
Salt	0.3	Salt	0.3
Example 3	*Proportion (%)*	*Example 6*	*Proportion (%)*
Alfalfa hay	67.7	Alfalfa hay	59.2
Maize	31.5	Grain sorgum	40.0
Dicalcium phosphate	0.5	Dicalcium phosphate	0.5
Salt	0.3	Salt	0.3

Note: It is recommended that hays be ground and grains be rolled or ground. Components of these examples may be used as supplements for cattle grazing forage if relative nutritional values of forage are known.

sealed and frozen in liquid nitrogen. Semen that is processed and stored properly can be kept almost indefinitely. Many examples exist where calves have been sired through AI by bulls that died many years back. AI in cattle is physically convenient because the size of the rectum easily allows a person's arm to be inserted and physically guide the insemination syringe to and through the cervix (which is a landmark structure used in cattle AI). Many fixed-time AI protocols have been developed in recent years where cows or heifers are inseminated at a set time following estrus synchronization as opposed to visual observation for estrus.

Male Considerations

Several research trials have been conducted that show semen quality and scrotal circumference increase dramatically for 4–6 months following puberty. As a result, it should not be assumed that a bull is fully fertile because it has reached puberty.

Table 11 Sample rations for growing cattle

Ration 1		*Ration 2*		*Ration 3*		*Ration 4*		*Ration 5*	
Item	*Kg day*$^{-1}$	*Item*	*Kg day*$^{-1}$	*Item*	*Kg day*$^{-1}$	*Item*	*Kg day*$^{-1}$	*Item*	*Kg day*$^{-1}$
Dry hay – 12% protein	5.5	Dry hay – 15% protein	5.2	Dry hay – 15% protein	2.5	Dry hay – 15% protein	0.5	Dry hay – 15% protein	0.5

Figure 5 Nellore bulls in Brazil fed corn plant-based diet. The picture on the right shows the ration in the feed bunk (trough) that consisted mainly of maize (corn) plants (stalk and leaves and cobs with grain) that had been ground.

Puberty is the ability to impregnate heifers or cows, not the ability to be a herd sire. It is also recognized that puberty in bulls occurs close to when the bull has 26–28 cm of scrotal circumference, and the age at which this happens can vary widely across breed types. Table 14 shows scrotal circumference in bulls across ages in several breeds.

Some indication of the bulls' potential to impregnate females is needed before the breeding season and is typically accomplished through a breeding soundness examination or breeding soundness evaluation, which considers scrotal circumference but includes more detailed information (Table 15).

Controlled Breeding and Calving Seasons

Farm and ranch managers make decisions, plan activities, and pay bills on a regular repeating time schedule. The challenge from cow-calf production is to make the animals reproduce annually in a timely manner. As a result, a target annual calving interval of 365 days is the goal for beef cows. The closer the calving interval is to 365 days, the easier it is to keep the cows on a repeating annual production cycle. Reproductive management for beef cows revolves around having a short and controlled calving season. It is typical that beef cows will not return to estrous activity until approximately 30 days or more

Table 12 Example of feedlot rations with varying amounts of grain and associated nutritional analyses from a study evaluating feed transition time

Item	*Proportion of concentrate (grain plus supplement) in diet (%)*[a]						
	40.0	*48.3*	*56.7*	*65.0*	*73.3*	*81.7*	*90.0*
Ingredients (% of DM)

N (kg day^{-1})	0.15	0.14	0.14	0.14	0.18	0.12	0.12
P (kg day^{-1})	0.05	0.05	0.05	0.04	0.07	0.04	0.04
K (kg day^{-1})	0.12	0.09	0.11	0.10	0.14	0.10	0.08

[a]Values from Hamilton (2004). Weight is total mass of urine and feces excreted; volatile solids refer to mass percentage of total solids that will ignite when heated to 550 °C; Chemical oxygen demand (COD) is related to amount of oxygen required to digest manure; carbon to nitrogen ratio (C:N) is related to stability.
[b]The calculation for daily manure production in the examples comes from taking the appropriate rate for the size class in accordance with the animal's weight (for instance daily manure solids from a 550 kg cow takes the rate of 3.31 kg day^{-1}/454 kg of weight and multiplies this value by the ratio of the animal's weight of 550 kg as compared with the standard rate, or 3.31 kg is expected from a 454 kg cow, but a 550 kg cow is expected to produce 550/454 = 1.21 times as much, or 4.0 kg, etc.).

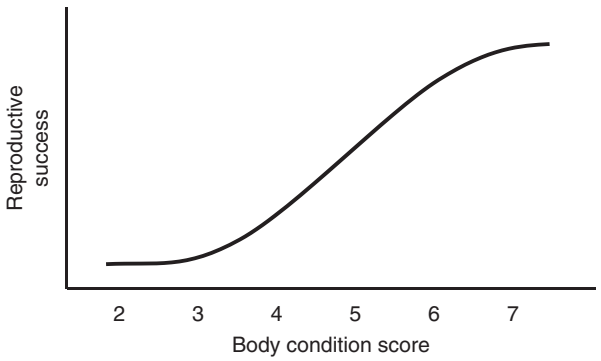

Figure 6 General relationship of body condition score (1–9 scale) of beef females and fertility.

after calving. Gestation length in beef cattle is approximately 283 days among many *B. taurus* breeds, 285 days among *B. indicus–B. taurus* crosses, and approximately 290 days in *Bos indicus* (Zebu). As a result of maintaining a 365-day calving interval, there will only be 365 − 285 − 30 = 50 days in which cows can breed back. The time of the year when calves are born should be based on the forage reserves in pastures (or feed costs) in order to coordinate the times of greatest nutritional requirements with the times of most available/cheapest feed costs to minimize annual cow maintenance cost. If feed resources are not adequate, cows will lose body condition after calving, and this will lengthen the postpartum anestrous period. In many harsh environments, particularly when supplemental feed cannot be offered, a very low percentage of cows may calve annually (Figure 7).

The length of time for the calving season is also important. Many production records for contemporary groups are based on individuals that are born within a 90-day period (individuals within this age range can be fairly compared with one another for performance traits). As a result, if all individuals within a herd (and there could be multiple herds within a ranch) are born within this 90-day window, they can be classified as a single contemporary group, provided they are all managed the same. Many people assume that the length of the breeding season will be exactly the same as the length of the calving season, but the length of the calving season will usually be 10–14 days longer because there is individual variability in gestation length. So, if a 90-day calving season is the target, then a 75-day breeding season is recommended. A 60-day breeding season should result in a 75-day calving season, etc.

Early Weaning

In many geographical areas it is common to wean calves at an average age of approximately 7 months. There is nothing magical about this calf age for weaning, but many breed societies or associations adjust weaning weight to a standardized calf age (200 days, 205 days, etc.). Some producers weigh calves around this age to submit weights to breed societies, but keep calves on the cows until 9 or 10 months of age. Many

Table 14 Reported mean scrotal circumference (cm) across ages in beef breeds

Table 15 Components of bull breeding soundness exams

General physical health	*Reproductive tract*	*Semen evaluation*
Assessment of overall health – evaluation of the eyes, structural soundness, knee and hock joints, body condition score, and parasite infestation	Physical palpation and visual evaluation of reproductive organs – penis, prepuce or foreskin, sheath, scrotum and testicles, and secondary sex glands such as prostate and seminal vesicles	Evaluation of actual ejaculate – semen color, number of live cells, live to dead cell ratio, motility of cells, and abnormalities

Note: Although only semen evaluation traits are given a score, the failure in any category can result in failure of the overall breeding soundness exam. Libido or serving capacity is not evaluated as a component of breeding soundness exams under the Society of Theriogenology (USA) but is included under the Australian Association of Cattle Veterinarians (McGowan *et al*., 1995) evaluation. The Western Canadian Association of Bovine Practitioners (Barth, 2000) has a spot on the form for libido assessment but states the producer of the bull should evaluate this.

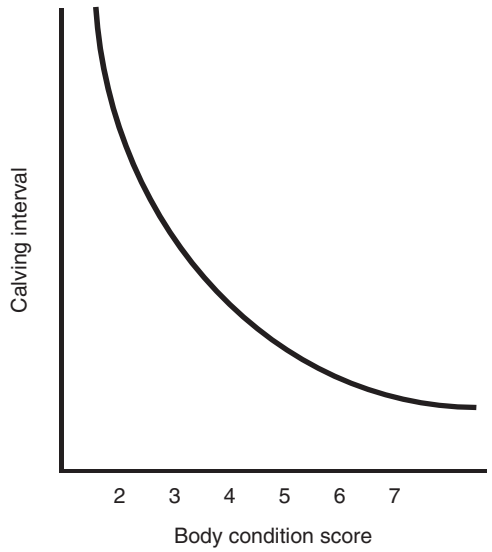

Figure 7 General relationship of body condition score (1–9 scale) of beef females and time between birth of calves (calving interval).

commercial producers wean calves when they are approximately 6–8-month old on average. Some producers may let cows wean the calves on their own; under extensive conditions a cow will usually stop nursing its calf when it is getting closer to having another calf, but not always. Other commercial producers may wean calves early at approximately 60–90 days of age. Weaning at this young age has widely reported reproductive advantages for the cows. There is a direct neural feedback mechanism triggered when a cow has its calf weaned, which typically instigates estrous activity and shortens postpartum anestrous.

Reproductive measures can be monitored at (1) the herd level, (2) the individual cow level, and (3) the individual bull level. All producers have the ability to measure herd level reproductive measures if they have adequate inventory numbers, and these herd level measures provide benchmark values to monitor herd performance over time. Many cow- and bull-level reproductive measures require individual animal identification and represent a higher level order of data collection and decision making. No strategies to improve reproduction will be able to compensate for inadequate nutrition. Recording of important performance measures in herds will set benchmark values to monitor reproductive success within and across years. There are many reproductive technologies that may be of varying benefit under different circumstances, but these need to be evaluated relative to cost versus benefit on a case-by-case basis.

Health

There are many diseases in cattle that need to be considered. Some are specific to regions and some are global in their occurrence. The readers may refer to local sources for specific diseases that may limit production in their area(s), as this is beyond the scope of this article. The basis for monitoring and maintaining the health of cattle begins with understanding typical normal and abnormal signs of animals (Table 16) and understanding that proper nutrition and sanitation are key

Table 16 Expected signs and values of healthy cattle

Sign	*Expected normal value*	*Abnormal indications*
Rectal temperature	38.5 °C (101.5 F)	Many antimicrobial products are administered when higher than 40 °C
Breaths per minute	30	Rapid, shallow breaths; long pauses between breaths
Heart beats per minute	60–70	Slow and rapid heart rates can result from a variety of causes
Nose	Beads of perspiration, shiny, and even skin	Dry, very warm to touch, and cracked or scaly surface
Eyes	Moist, smooth and shiny, and brown iris	Dull and nonreflective, unusual color or presence of growths
Demeanor[a]	Alert, but at ease; attentive but not combative	Actions that substantially deviate from 'normal' behavior
Feces	Greenish color, not extremely dry or watery; makes a plop sound and forms patties/pads	Color may be dark, light, grayish; consistency too firm or too loose; appearance of blood
Movement[a]	Even and smooth actions of walking, moving neck, standing, and no trembling	Limping, shaky in movements such as walking, holding head at unusual angle, and wobbly or jerky
Hair appearance	Shiny and evenly distributed	Dull without luster, patchy areas of thin or lost hair, and unusual color

[a]What is 'normal' behavior as well as other traits can vary drastically across individuals and circumstances (such as with a newborn calf), and abnormal is a marked deviation from what is typical. History of observation provides useful information. Documentation of these signs that are suspected to be abnormal will aid veterinarians in diagnoses.

Table 17 Summary statistics for hair coat characteristics and sweating rate for Braford cows in Mato Grosso do Sul (Brazil)

Trait	*Mean*	*SD*	*CV (%)*	*Minimum*	*Maximum*
Coat thickness (mm)	3.73	1.72	46.1	1.00	13.00
Hair number (hair cm^{-2})	993	504	50.8	319	4852
Hair length (mm)	10.41	3.91	37.6	4.13	26.50
Hair diameter (μm)	30.98	8.13	26.2	11.00	69.00
Coat reflectance (%)	18	13	72.2	1	63
Sweating rate ($gm^{-2}\ h^{-1}$)	319.97	83.02	25.9	89.20	591.48

Note: Based on 1607 observations across heifers and cows through 5-year-olds in a single commercial herd. Females were generated from 33 sires and varied in breed composition from 25% Hereford–75% Nelore to 75% Hereford–25% Nelore.

Source: Reproduced from Bertipaglia, E.C.A., da Silva, R.G., Cardoso, V., Fries, L.A., 2007. Hair coat characteristics and sweating rate of Braford cows in Brazil. Livestock Science 112, 99–108.

elements for all cattle health programs. Health problems of beef cattle may originate from infectious microbial pathogens, internal and external parasites, digestive disorders, ingestion of toxic substances, and genetic lines.

The World Organisation for Animal Health (OIE) is a valuable resource for information on major livestock diseases, and there is much useful information at its web site. Efforts to control animal diseases at the global level led to creation of the Office International des Epizooties (hence OIE) in 1924. In 2003 the name became the World Organisation for Animal Health but kept its historical acronym of OIE. It is responsible for improving animal health worldwide, is recognized as a reference organization by the World Trade Organization, and as of 2013 had a total of 178 member countries. Another valuable resource free of charge for both animal health professionals and the general public is the Merck Veterinary Manual online with searchable databases.

Adaptation

Cattle as a species are quite remarkable in that they can exist in very extreme climatic conditions. However, this does not mean that all types of cattle can equally exist in all conditions. Cattle can adapt to harsh cold climates as well as tropical environments. Two terms that should be discussed here are acclimatization and adaptation. Acclimatization refers to an animal's ability to adjust to or cope with a new environment, and this can happen over a few days, weeks, or months. Acclimatization deals with the concepts of the processes in an animal operating differently to achieve homeostasis under new conditions. Adaptation, however, is a genetic concept and means a group of animals changing genetically so that they are better genetically suited to a particular environment; it is more of an evolutionary development concept (Table 17).

Behavior and Welfare

There is no substitute for regular observation of cattle behavior to help understand components of beef cattle production. Understanding of 'normal' and 'abnormal' behaviors in general as well as observation and recognition of individual animal differences for what are 'normal' and abnormal' are also very important. Cattle, as most animals, can and will respond to a wide variety of stimuli, including training. Training with regard to proper handling techniques can reduce stress levels for both animals as well as personnel. Design of cattle handling equipment and facilities can complement (or inhibit) animal experiences and the effectiveness of training

Table 18 Recommendations about space and rest for cattle hauled long distances and small calves

Cattle size 500 kg	*Travel duration (h) Up to 12 h*	*Floor space allowance (m^2) 1.35*	*Travel duration (h) More than 12 h*	*Floor space allowance (m^2) 2.03*
	First travel period (h)	*First rest (h)*	*Second travel period (h)*	*Second rest (h)*
Calves less than 6 months	8	6	8	24
Cattle more than 6 months	12	6	12	24
	Floor space for young calves of different sizes			
Weight	Up to 55 kg	55–110 kg	110–250 kg

effort. Behavior of cattle is as important when they are not under the influence of managers as when they are being processed through facilities or being transported. Cattle modify their behavior in response to conditions that are deemed unfavorable to alleviate stress, such as seeking shade to reduce heat stress or seeking cover and separation from the herd before giving birth. Overall, welfare and well-being of cattle is very important to their production efficiency and longevity, and documentation of proper cattle welfare management techniques is likely to become more important for some consumers and regulatory agencies (Tables 18 and 19).

There are many behaviors that are inherent to cattle, such as how they use their tongue and mouth during grazing, how females stand to be mounted or mount other females as they are in heat, etc., and many of these types of behaviors have been discussed in the preceding section. However, there are also aspects of behavior referred to as temperament or disposition that describe inherent differences about how cattle respond to certain handling or stressful situations.

It is widely recognized that cattle may be trained to perform many different tasks or activities. What producers may not recognize is that animals have to be trained in many aspects related to production, such as how to drink out of a water trough or eat out of a feed bunk when calves go from a ranch to a feedlot, but they can also be trained for things such as how to utilize pastures and how to proceed through working facilities. Providing supplemental feeding, placement of salt and mineral licks, addition of watering sources, etc. can be very useful to influence how animals utilize large pastures. Likewise, handling cattle calmly and quietly as they are moved from pasture to pasture or through alleys and chutes of working facilities will make the same task much easier in the future because the animals are not stressed by this manner of handling, and they will be less adverse to similar situations in the future. Proper cattle-handling and transportation guidelines are now viewed as important aspects of beef quality assurance programs, and it is important for cattle producers to think about the impacts of how they handle their cattle, not just for their own future interactions with the same animals, but also that even though cattle are being sold from their operation, other people as well in the industry will interact with these animals. Previous handling and treatment of animals affect their perception of humans, working pens, and transportation and can impact production responses, such as health and meat quality.

Carcass and End Products

The ultimate value of beef cattle production in most settings is utilization of their various body components primarily for food and secondarily for other aspects, such as clothing. In dairies, milk production (quantity and quality) takes on a primary purpose; in other scenarios, ceremonial uses may be a primary use. No matter which of these primary uses exist, the conversion of cattle into food and other useful components is important. Where cattle are converted into end products for human consumption, sanitation is critical for protecting human health and minimizing risks of illness from potential pathogens. It is important to have inspection systems in order to ensure safety and wholesomeness of beef and associated end products and by-products. Grading or classification of beef carcasses and associated products based on specific standards that relate to consumer satisfaction are needed for trade as well as consumer confidence (Figure 8).

Several factors have been shown to impact beef carcass yield and composition. A general range for the dressing percentage (ratio of carcass weight to live weight) of cattle is 52–68%, depending on degree of body condition and muscle expression. In discussing factors that impact beef carcass composition, it must be emphasized that there is considerable variability within and across all factors, and stereotypes cannot be accurate predictors in many cases.

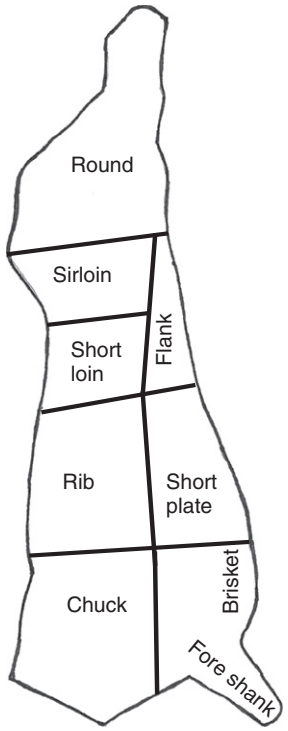

Figure 8 General descriptors for wholesale cuts from beef carcasses. Exact locations of distinction between these cuts may vary across countries or markets. Wholesale cuts are further fabricated into retail cuts, the names of which may vary drastically across countries.

Genetics

Within *B. taurus*, biological type of British-based versus Continental European-based differences exist with regard to tenderness, marbling, and muscle deposition that correspond to differences in growth rate, weight at the time of slaughter, and fatness at slaughter. British types seem to have slight advantages in tenderness when other composition factors are held constant, but increase in tenderness in several cases when differences in other factors, such as fat thickness, time on feed, etc., are not equal. Continental European cattle tend to be taller, have heavier and more muscular carcasses at a constant fat thickness, and require a longer time on high-energy diets to reach a constant fat endpoint. The two main differences (related to genetics) between *B. taurus* and *B. indicus* cattle relate to tenderness associated and degree of marbling, where *B. taurus* (particularly British type) has advantages in both traits. Certain genetic types, such as Japanese Black (Wagyu) and Korean Hanwoo, have extremely high marbling potential, particularly when fed for long times; other genetic types, such as double-muscled breeds like Belgian Blue, Piedmontese, etc., have very little marbling.

Physiological Age

Age is associated with palatability, which is usually assessed by skeletal ossification and dentition but may also be indicated by lean muscle color. Increased age is associated with reduced palatability, particularly in cattle more than 42-month old. Contractile state of muscle and the amount of connective tissue affect tenderness but are not significantly different between breeds and differ due to animal age and sex.

Table 20 General compositional aspects of market weight beef, pork, and lamb

Trait	*Beef*	*Pork*	*Lamb*
Average live animal weight (kg)	454–544	95–104	45
Age (months)	36	6	8–12
Dressing percentage (ratio carcass/live weight)	60	70	50
Carcass weight (kg)	272–318	68–73	23
	Carcass composition (%)		
Lean	52	50	55
Fat	32	32	28
Bone	16	18	17

Nutrition

Higher planes of nutrition will speed up growth rate as well as fat deposition. Type of diet, such as grass-fed versus concentrate-fed diet, and even type of forage and grain can impact color, flavor, and fatty acid profile. Differences in marbling are thought to be driven primarily in differences in external fat thickness. Differences in tenderness appear to be a function of differences in age.

Growth-Promoting Hormones and Hormone-Like Compounds

Testosterone, estrogen, progesterone, and synthetic derivatives found in growth-promoting implants as well as beta-agonists administered through feeds increase rate of gain, efficiency of gain, and red meat yield by increasing muscle deposition at the expense of fat deposition. Extremely intense use of growth-promoting hormone products may reduce tenderness. Marbling may be reduced as a function of reduced external fat.

Environmental Stresses

How animals handle stress can affect energy metabolism. This may be due to illness as severity of bovine respiratory disease has been shown to reduce carcass marbling; impacts on tenderness do not seem to be obviously impacted but have not been intensely studied. Energy used to conserve and dissipate body heat can affect efficiency of gain and carcass composition when conditions are drastically different from the thermoneutral zone. Long-term stress is thought to increase risk of producing 'dark cutting' beef (color of the lean muscle is much

Table 21 Expected percentages of live weight and weights for various by-products from cattle of different biological type (550 kg live weight basis at external fat of 10–12 mm)

darker than typical and is not the color that consumers are accustomed to).

Animal Sex Class

Differences exist in bulls versus steers versus heifers for muscle, fat, and bone growth patterns and percentages. In general, the ranking from bulls to steers to heifers are: (1) leanest to fattest, (2) most muscular to least muscular, (3) longest time to shortest time to reach a fat constant endpoint, and (4) lowest marbling to highest marbling (Table 20).

Cattle By-Products

Parts of the animal's body that do not remain with the carcass are collectively referred to as offal, and most of these items can be useful by-products, some edible, others not. Hooves may be used for dog treats and horns may be used as containers (such as for gun powder, historically) or for decorations. Some items that are made in part with inedible cattle by-products include cosmetics, explosives, and numerous leather products. Edible by-products include the heart, liver, pancreas, kidneys, stomach, tail, head, and several other components. Since recent bovine spongiform encephalopathy (BSE, or mad cow disease)

Table 22 Uses of edible by-products obtained from cattle

Raw by-product	*Principle use*
Brains	Variety meat
Heart	Variety meat
Kidneys	Variety meat
Liver	Variety meat
Spleen (melt)	Variety meat
Sweetbreads (pancreas)	Variety meat
Tongue	Variety meat
Oxtails	Soup stock
Cheek and trimmings	Sausage ingredient
Beef extract	Soups and bouillon
Blood	Sausage component
Fats from cattle and calves	Shortening, candies, and chewing gum
Stomach	
Suckling calves	Rennet for cheese making
Beef (reticulum and rumen)	Sausage ingredient, variety meat (tripe)
Intestines, small	Sausage casings
Intestines, large (beef and pork)	Sausage casings
Esophagus (weasand)	Sausage ingredient
Bones	Gelatin for confectioneries, ice cream, and jellied food products
Calf skin trimmings	Gelatin for confectioneries, ice cream, and jellied food products

outbreaks, it is not recommended to consume brain of other mammals by humans because the organism that causes BSE is found in the central nervous system of the infected cattle. As a result, the brain, spinal cord, and major nerves close to the spinal column are not consumed. This is also why feeding of ruminant-derived meat and bone meal to ruminants has been banned in most countries. The one thing of the animal that has little value associated with its weight is feed in the stomach, and animals are generally withheld from feed for several hours before harvest as this simply adds lost weight to the viscera. Animals are not withheld from water before harvest as dehydration could add to stress and impede exsanguination and hide removal.

The single most valuable by-product in most instances is the hide for the leather industry. In many countries during the industrialization age, the majority of the leather was used for draft livestock harnesses and associated accessories, but with the advent of increased mechanization for farming and transportation, the demand for this purpose was transferred to manufacturing and use of leather belts. As this trend passed, the footwear industry became the main use of leather from cattle. Romans *et al.* (2001) summarized this trend for North America. **Table 21** shows some expected percentages and weights of various by-products than can be expected from cattle.

In some markets, the variety meats may be a less valuable source of income than the carcass, but in other markets that collective value of the variety meats may be equal to or even exceed the value of the carcass. When there are regional or cultural differences in demand for these different types of products, this provides much trade potential and the possibility of added value for new markets. **Table 22** provides a summary of some different uses of edible by-products from cattle, and **Table 23** provides some nutritional values for some variety meat examples.

Use of inedible by-products

Numerous uses for various inedible by-products from cattle exist. Many organs and glands have compounds that can be extracted for human medicine and biomedical uses, several of which are summarized in **Table 24**. Also, several products or compounds can be used in a variety of industrial and manufacturing processes and uses, and many of these are provided in **Table 25**.

Table 24 Uses of organs and glands from cattle

Lungs – heparin (blood thinner), pet food
Heart – pericardium patches
Trachea – chondroitin sulfate (arthritis treatment)
Tendons – elastin and peptone
Gall bladder – cleaning agent for leather, paints, and dyes
Intestines – glycosaminoglycans (for cartilage and joint treatment), sutures, musical strings, and sport racquet strings
Liver – catalase, used in contact lens care products
Pancreas – insulin, chromotrypsin, and glucagons
Placenta – glycosaminoglycans, alkaline phosphatases, and fetal bovine (calf) serum
Testicles – hyaluronidase (cartilage and joint treatment)
Umbilical cord – hyaluronic acid
Uterus – glycosaminoglycans
Spinal cord – historically pharmaceuticals, laboratory reagents, source of neural lipids, and cholesterol
Bile – bile acids used to make industrial detergents and bilirubin to measure liver function
Nasal septum – chondroitin sulfate
Nasal mucosa – heparin
Bone – charcoal ash (for refining products such as sugar), ceramics, cleaning and polishing compounds, and bone and dental implants

Table 25 Summary of some uses of inedible by-products from cattle

Blood

Cell culture laboratories: Bovine serum albumin provides a wide variety of macromolecular proteins, low molecular weight nutrients, carrier proteins for water-insoluble components, and other compounds necessary for *in vitro* growth of cells, such as hormones and attachment factors. Serum adds buffering capacity to the medium and binds or neutralizes toxic components in the growth milieu.

Home and industrial uses: Plywood adhesives, fertilizer, foam fire extinguisher, and chemical fixer for dyes

Fatty acids (derived from tallows)

General uses: Plastics, tires, candles, crayons, cosmetics, lubricants, soaps, fabric softeners, asphalt emulsifiers, synthetic rubber, linoleum (metallic stearate), PVC (calcium stearate), jet engine lubricants, carrier for pesticides and herbicides, wetting agents, dispersing agents, defoamers, solubilizers, and viscosity modifiers

Many specific examples (oleic acid, stearic acid, etc.) are used for specific purposes or products

Tallow (fats and oils derived from meat, bone, hooves, and horns)

Various industrial tallows used as lubricants and greases: Top White Tallow, All-Beef Packer Tallow, Extra Fancy Tallow, Fancy Tallow, Bleachable Fancy Tallow, Prime Tallow, Special Tallow, No. 2 Tallow, A Tallow, Choice White Grease, and Yellow Grease

Collagen (derived from connective tissues and beef hides)

Numerous uses: Hemostats, vascular sealants, tissue sealants, orthopedic implant coatings, vascular implant coatings, artificial skin, bone graft substitutes, corneal shields, injectable collagen for plastic surgery, injectable collagen for incontinence treatment, meat casings, food additives, artificial dura maters, dental implants, wound dressings, antiadhesion barriers, platelet analyzer reagents, research reagents, antibiotic wound dressing, and lacrimal plugs

Glycerin products (derived from tallows)

Glycerin derivatives: A wide range of pharmaceuticals, including cough syrups and lozenges, tranquilizers, eyewashes, contraceptive jellies and creams, ear drops, poison ivy solutions, solvent for digitalis and intramuscular injection, sclerosing solutions for treatment of varicose veins and hemorrhoids, suppositories, and gel capsules

Glycerol: Solvent, sweetener, dynamite, cosmetics, liquid soaps, candy, liqueurs, inks, lubricants, antifreeze mixtures, and culture nutrients for antibiotics

Gelatin (derived from collagen)

Nonfood uses include cosmetics, industrial uses, photographic paper, and photograph development as an aid in binding for glues, adhesives, and emulsion and as a binder in pills and suppositories

Global Cattle and Beef Comparisons

Finally, some discussion is provided regarding beef production across regions of the world. Differences in these values occur due to combinations of production resources, genetic types of cattle, management practices, cultural preferences, and various political issues. Table 26 provides numbers of cattle (number of head), whereas Table 27 provides values for production, consumption, and trade (in kg of beef on a carcass weight, or bone-in, basis). For both of these tables, countries (or region

Table 27 Top 10 rankings for beef production and trade amounts by country for year 2012

Rank	Total production		Domestic consumption		Imports		Exports	
	Country	Amount	Country	Amount	Country	Amount	Country	Amount
1	USA	11 855	USA	11 744	Russia	1023	Brazil	1524
2	Brazil	9 307	Brazil	7 845	USA	1007	India	1411
3	EU-27	7 765	EU-27	7 806	Japan	737	Australia	1407
4	China	5 540	China	5 597	South Korea	370	USA	1114
5	India	3 460	Argentina	2 458	EU-27	348	New Zealand	517
6	Argentina	2 620	Russia	2 395	Canada	301	Uruguay	355
7	Australia	2 152	India	2 049	Egypt	250	Canada	335
8	Mexico	1 820	Mexico	1 835	Hong Kong	241	EU-27	307
9	Pakistan	1 400	Pakistan	1 367	Venezuela	220	Paraguay	251
10	Russia	1 380	Japan	1 255	Mexico	215	Mexico	200
	World	57 170	World	55 513	World	6683	World	8324

Note: Values are reported in millions of kg and are on carcass weight equivalent basis.

for EU-27) are listed from 1 to 10 in ranking within each category along with their respective values.

New and Emerging Technologies

There are numerous technologies available to assist in beef cattle production. Reproductive tools such as nonsurgical embryo transfer, *in vitro* fertilization (IVF), and sexed semen are available and used to varying degree (and in combinations) among seedstock and commercial cow-calf producers. Sequencing of the bovine genome and numerous research efforts in beef cattle genomics have allowed the development of numerous genetic tests for a variety of beef cattle traits, and the field of genomic selection is being explored by many beef cattle groups. An increased focus on individual animal efficiency for feed utilization and many other traits has led to improved animal identification and evaluation systems that rely on automated data capture. There are more tools available to beef cattle producers worldwide than many thought ever possible just a few years ago. Beef cattle producers must prioritize and evaluate their financial information in conjunction with production information in whole systems considerations in all cases and weigh costs versus benefits for use of any technology.

Summary

Beef cattle are very useful in a wide range of production environments globally to supply a wide array of products. The weight and amount of muscle in beef cattle are important in many cultures. In some cases, it is the older animals that are utilized for beef after they have been utilized for draft purposes; however, it has been the assumption throughout this article that production of cattle for beef carcass markets is a primary goal. This article has not discussed many specific considerations involved in beef cattle production but has attempted to point out unique aspects of beef cattle production that might be different in other livestock species. General principles for breeding, genetics, nutrition, reproduction, health, and welfare are similar across livestock species, but specific knowledge and management within each species (as well as within combinations of animal resources, production environment, and local markets) are crucial for short-term as well as long-term economic success.

Glossary

Agroecology The application of ecological concepts and principles to the design and management of sustainable agroecosystems.
Agroecosystems Agricultural ecosystems including biophysical and human components and their interactions.
Biodiversity The variation of life in all forms from genes, to species, to communities, to whole ecosystems.
Ecosystem service providers Organisms, guilds, and ecological communities that are biological mediators of ecosystem services, providing services through their functions and interactions.
Ecosystem services Functions of ecosystems – including agroecosystems – that are useful to humans or support human well-being: (1) provisioning services include the production of food, fuel, fiber, and other harvestable goods; (2) regulating services include climate regulation, flood control, disease control, waste decomposition, and water quality regulation; (3) supporting services include the foundational processes necessary for production of other services, including soil formation, nutrient cycling, and photosynthesis (primary production); and (4) cultural services provide recreational, esthetic, spiritual, and other nonmaterial benefits.
Human well-being A context- and situation-dependent state that comprises basic material for a good life, freedom and choice, health, good social relations, and security.
Millennium Ecosystem Assessment An international synthesis released in 2005, created by more than 1000 of the world's leading scientists, that analyzed the state of the Earth's ecosystems.
Payment for ecosystem services Market-based instruments used to channel investment in ecosystem services.
Resilience The capacity of a system to absorb disturbance and retain structure and function; this includes the human capacity to anticipate and plan for the future (e.g., in managing agricultural systems).
Scale Geographical extent; relevant scales for agroecosystems often include units commonly used in management and decision making, such as field (local and on-farm cultivated area), farm (including cultivated and noncultivated areas), landscape, regional, and global.

Introduction

Historically, agricultural systems have been managed, above all, for the production of food and fiber; however, agricultural landscapes can provide a wide range of goods and services to society. 'Ecosystem services' are those functions of ecosystems – including agroecosystems – that are useful to humans or support human well-being (Daily, 1997; Kremen, 2005). The ecosystem services concept is remarkably longstanding. Mooney and Ehrlich (1997) noted that in approximately 400 BC, Plato observed how forests provided important services to Attica and forest loss resulted in drying springs and soil erosion. Plato's work highlights that people have been aware of these critical services long before the dawn of industrial agriculture (Rapidel *et al.*, 2011).

In the past two decades, work at the interface of ecology and economics to characterize, value, and manage ecosystem services has supported a paradigm shift in how society thinks about ecosystems and human relationships to them. As both major providers and major beneficiaries of ecosystem services, agricultural landscapes and the people within them are at the center of this shift. Growing calls for agriculture landscapes to be managed as 'multifunctional' systems create new mandates, as well as opportunities, to maintain and enhance ecosystem services as part of productive agroecosystems.

Work on multifunctional ecosystems draws on the Millennium Ecosystem Assessment (2005) and other recent evaluations of ecosystem services (e.g., The Economics of Ecosystems and Biodiversity and The Common International Classification of Ecosystem Services). The Millennium Ecosystem Assessment provides a globally recognized classification that emphasizes relationships between ecosystem services and human well-being and describes four types of services (The authors draw on the classification of ecosystems services used in Millennium Ecosystem Assessment throughout the article (MEA, 2005), recognizing that more recent classifications have minimized or eliminated supporting services in favor of specific, operational descriptions designed for environmental accounting (Haines-Young and Potschin, 2012) and economic valuation (TEEB, 2010)). Provisioning services include the production of food, fuel, fiber, and other harvestable goods. Regulating services include climate regulation, flood control, disease control, waste decomposition, and water quality regulation. Supporting services include the foundational processes necessary for production of other services, including soil formation, nutrient cycling, and photosynthesis (primary production). Cultural services provide recreational, esthetic, spiritual, and other nonmaterial benefits. Most classifications, despite their variations, consider interdependence between ecosystem services and human well-being as well as variation in ecosystem

services across spatial scales ranging from local to global (Figure 1).

Biodiversity – the variation of life in all forms from genes, to species, to communities, to whole ecosystems – is a significant determinant of ecosystem function and provision of ecosystem services. Although relationships between biodiversity and ecosystem services are complex and vary widely across different types of ecosystems, at the broadest level, increased native biodiversity is generally associated with higher levels of ecosystem services within a given system (Balvanera *et al.*, 2006; Cardinale *et al.*, 2012). Plant diversity, for example, has been found to enhance belowground plant and microbial biomass, which is associated with the ecosystem service of erosion control through the effects of large root and mycorrhizal networks holding soil in place (Balvanera *et al.*, 2006). It is also important to note that some ecosystem services are provided in part by the abiotic (nonliving) components of ecosystems, such as aquifers and inorganic portions of soils. Biodiversity can be considered a form of 'biological insurance' that helps to assure ecosystem performance, including providing ecosystem services, as diversity increases the chances that one or more species will be able to perform critical functions, even in the event of disturbance or species loss (e.g., natural disaster and human-induced land use change) (Naeem and Li, 1997).

Agroecosystems both provide and rely on ecosystem services to sustain production of food, fiber, and other

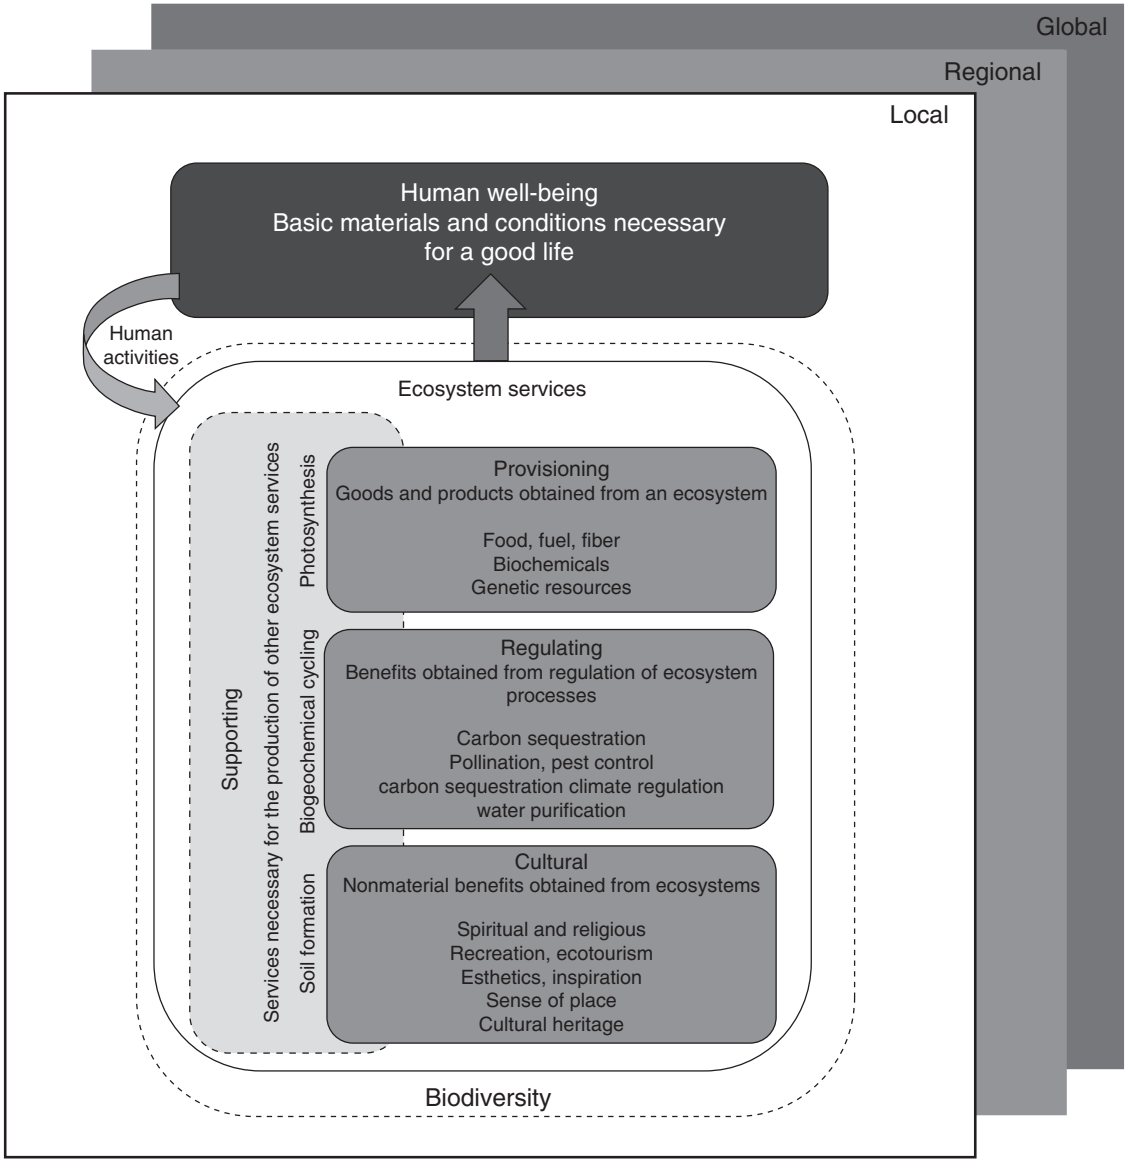

Figure 1 Typology of ecosystem services. This ecosystem service typology, adapted from the Millennium Ecosystem Assessment (MEA, 2005), considers biodiversity as a foundation for all ecosystem services (represented with a dotted line framing ecosystem services). Ecosystem services include provisioning, regulating, and cultural services (dark gray boxes, solid outline), as well as supporting services (light gray box, dashed outline). Ecosystem services support human well-being (charcoal gray box, white text), and, in turn, are influenced by human activities and land-use management decisions. Both ecosystem services and human well-being can be considered at nested spatial scales from local, to regional, to global.

harvestable goods. Many services have on-farm benefits (e.g., for farmers, plantation managers, and other people on-site), whereas others have broader public benefits to off-farm users; some benefit both groups (Table 1).

The evaluation and management of ecosystem services in agricultural landscapes has emerged as a top priority for several reasons. First, agricultural ecosystems – including croplands and pastures – are among the largest terrestrial

Table 1 Ecosystem service descriptions and related on-farm benefits and public, off-farm benefits

Ecosystem service	*Description*	*On-farm benefits*	*Public, off-farm benefits*
Provision of food, fuel, fiber, and biochemicals	Harvestable goods from agroecosystems	Food and other goods for on-farm consumption or sale	Goods for agricultural markets
Soil structure and fertility enhancement	Soil structure and processes of nutrient cycling and delivery of nutrients to plants; processing organic matter and transforming detritus and wastes	Support for crop growth; can limit need for chemical fertilizers	May limit need to mine or manufacture chemical fertilizer
Erosion protection	Soil retention; limiting soil loss through wind and water erosion	Maintain soil, and the nutrients it contains, to support production	Potential reduction of sediment transfer to downstream systems & users
Hydrologic services: Water flow regulation	Buffering and moderation of the hydrologic cycle, including water infiltration into soils and aquifers, moderation of runoff, and plants transpiration	Water in soils, aquifers, and surface bodies available to support plant growth	Stabilize stream base flow and mitigate flooding to downstream areas; recharge into aquifers and bodies of water; plant transpiration may support precipitation patterns
Hydrologic services: Water purification	Filtration and absorption of particles and contaminants by soil and living organisms in the water and soil	Clean water available for human consumption, irrigation, and other on-farm uses	Clean water available to downstream users
Pollination	Transfer of pollen grains to fertilize flowers	Necessary for seed set and fruit production in flowering plants and crops	Necessary for outcrossing in noncultivated flowering plants
Pest control	Control of animal and insect pests by their natural enemies – predators, parasites, and pathogens	Minimize crop damage and limit competition with crops	May limit need for pesticides that threaten environmental and human health
Weed control	Botanical component of pest control; suppressing weeds, fungi, and other potential competitors through physical and chemical properties of cover crops, intercrops, and other planted elements	Minimize weed competition with crops	May limit need for herbicides that threaten environmental and human health
Carbon sequestration	Atmospheric carbon dioxide is taken up by trees, grasses, and other plants through photosynthesis and stored as carbon in biomass and soils	Few demonstrable on-farm benefits[a]	Regulation of the carbon cycle; mitigation of greenhouse gas contributions to atmospheric change
Genetic resources	Pool of genetic diversity needed to support both natural and artificial selection	Distinct genotypes (cultivars) allow fruit set in orchards and hybrid seed production; trait diversity (from landraces and wild relatives) supports disease resistance, new hybrids, and climate adaptations	Prevention against large-scale crop failure
Cultural and esthetic services	Maintaining landscapes that support: esthetics and inspiration; spiritual and religious values; sense of place; cultural heritage; recreation and ecotourism	Esthetics and inspiration; spiritual and religious values; sense of place; cultural heritage; recreation and ecotourism	Esthetics and inspiration; spiritual and religious values; sense of place; cultural heritage; recreation and ecotourism

[a]On-farm carbon sequestration can be associated with on-farm benefits in closely related ecosystem services, such as increased soil organic matter and microclimate regulation (e.g., shade provided by trees).

biomes and account for approximately 40% of the Earth's surface (Foley *et al.*, 2005). Second, increases in food and fiber production have often been achieved at the cost of other critical services. The Millennium Ecosystem Assessment (2005) reported that approximately 60% (15 out of 24) of services measured in the assessment were being degraded or unsustainably used as a consequence of agricultural management and other human activities. Finally, evaluations of 'planetary boundaries,' which describe the safe operating space for human activities with respect to the planet's biophysical systems and processes, indicate that modern, industrial agriculture is among the activities that have most significantly undermined the Earth's life-support systems (Rockström *et al.*, 2009). Major negative impacts have occurred through converting natural habitat to agriculture and infrastructure, environmental pollution, and environmental change induced by shifts in nitrogen and phosphorus use.

Recent work highlights the need for better understanding the ecological processes that underpin critical ecosystem services (Kremen, 2005). Provision of ecosystem services in farmlands is directly determined by their design and management (Zhang *et al.*, 2007) and strongly influenced by the function and diversity of the surrounding landscape (Kremen and Ostfeld, 2005; Tscharntke *et al.*, 2005). Yet, there is an outstanding need for field studies that describe the mechanisms, which control how ecosystem services vary across both space and time. Building understanding of the mechanisms underlying ecosystem services is also essential to developing the ability to predict how management activities will affect the single ecosystem services, and suites of services, needed to support both productive farmlands and human well-being.

Ecosystem Services and Disservices in Agricultural Landscapes

Ecosystem Services and Disservices

Agroecosystems both provide and rely on ecosystem services. Services that help to support production of harvestable goods can be considered services to agriculture (Zhang *et al.*, 2007). These services include soil structure and fertility enhancement, nutrient cycling, water provision, erosion control, pollination, and pest control, among others (**Figure 2**). Ecological

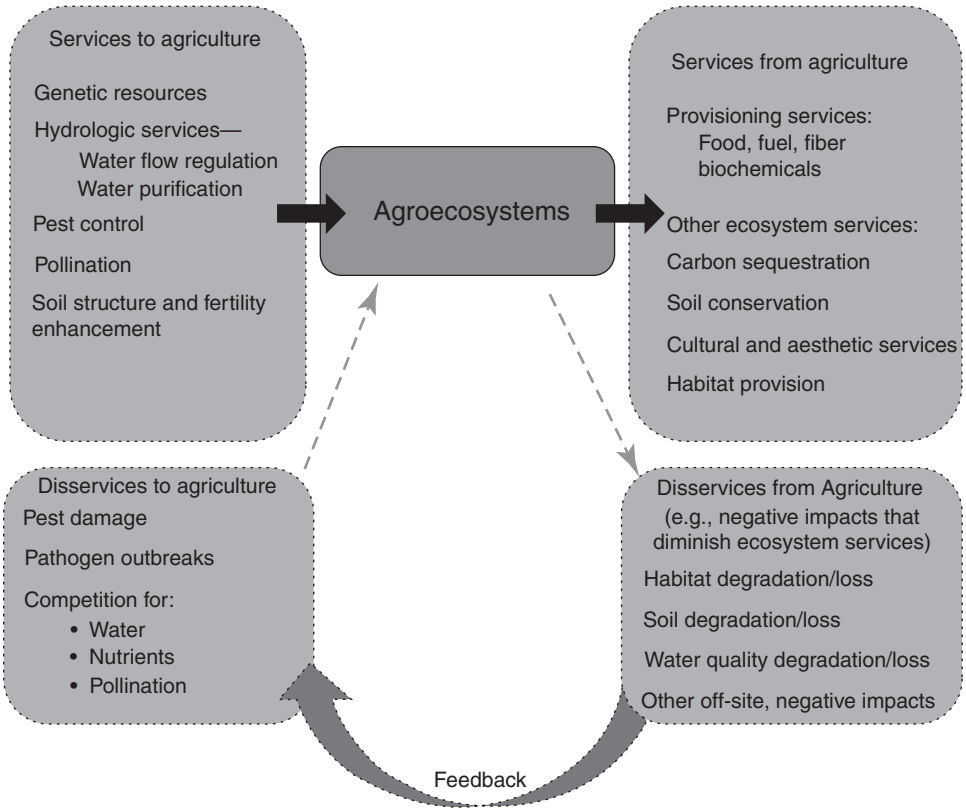

Figure 2 Ecosystem services and disservices to and from agriculture Farming systems can be both producers and beneficiaries of ecosystem services, and in many cases these relationships are deliberately managed by farmers. Such ecosystem services are represented by two gray boxes in the diagram. Production systems can also suffer from various disservices or contribute to disservices or loss of services. These negative relationships are usually the unintentional result of management action, represented by the two lower gray boxes and the dashed arrows. Disservices from agriculture can also lead to agricultural inputs and result in detrimental on-farm impacts, such as when habitat for natural enemies is removed and pest outbreaks increase, represented by the feedback arrow at the bottom of the diagram. Adapted from Zhang, W., Ricketts, T., Kremen C., *et al.*, 2007. Ecosystem services and dis-services to agriculture. Ecological Economics 64, 253–260 and Swinton, S., Lupi, F., Robertson, G., Hamilton, S., 2007. Ecosystem services and agriculture: Cultivating agricultural ecosystems for diverse benefits. Ecological Economics 64, 245–252.

processes that detract from agricultural production can be considered disservices to agriculture (Zhang *et al.*, 2007) and include pest damage, competition for water, and competition for pollination. Management of agricultural ecosystems also affects flows of ecosystem services and disservices (or diminution of naturally occurring services) from production landscape to surrounding areas. Services from agriculture include provisioning services (food, fuel, fiber, and biochemicals) as well as carbon sequestration, soil conservation, cultural and esthetic services, and habitat provision (e.g., providing habitat for endemic organisms). Disservices from agriculture can include degradation or loss of habitat, soil, water quality, and other off-site, negative impacts. Both services and disservices are typically a result of management practices within agricultural fields and landscapes. The remainder of this section describes some of the key ecosystem services that support agricultural productivity (summarized in **Table 1**) and disservices detract from it (see Swinton *et al.*, 2007 for detailed discussion of services and disservices from agriculture).

Services to Agriculture Help to Sustain Agricultural Productivity

Soil structure and fertility enhancement services include the processes of soil formation, structural development (including physical, chemical, and biological properties of soil), and nutrient cycling mediated by biotic and abiotic factors to support plant growth. These soil characteristics are important determinants of the quantity and quality of farming outputs (Zhang *et al.*, 2007). As soil organisms process dead organic matter, and their waste replenishes nutrients required for primary production, the fertility needed to support primary production is maintained (Daily *et al.*, 1997).

Soil structure is enhanced through the activities of macrofauna – such as earthworms, centipedes, millipedes, and isopods – that aerate soil by creating pores as they burrow through the soil profile, mixing organic and mineral particles, redistributing organic matter and microorganisms, and enriching soil with castings (Hendrix *et al.*, 1990; Edwards, 2004). A host of microfauna also act as biological mediators of soil fertility and structure. Their activities support soil fertility as they break down plant detritus and other organic matter, and incorporate nutrients into their biomass, which may otherwise move through the system or be lost downstream (Paul and Clark, 1996). Micro- and macrofauna (e.g., acarina and collembola) influence nutrient cycling by regulating bacterial and fungal populations, release energy by breaking down large molecules into smaller units (catabolizing organic matter), and mineralizing and immobilizing nutrients. Their activities influence soil structure by producing organic compounds that bind soil aggregates. Bacteria and fungi are also part of an important cadre of microflora that mediates nitrogen fixation from the atmosphere, transforming it into plant-available forms (Hendrix *et al.*, 1990).

Soil processes in agroecosystems are subject to removal of nutrient-rich biomass during harvest, plus elevated decomposition rates that increase with frequency of tillage and irrigation. In some systems, organic matter is also lost when fields are burned (e.g., to clear biomass for the next planting). Nutrient losses in agroecosystems contrast with unmanaged, undisturbed ecosystems in which nutrient cycles tend to be more nearly closed, with inputs approximately matching outputs (Daily *et al.*, 1997). Many high-intensity farming systems do not retain soil structure and fertility through biological processes, they are rather maintained through tillage and additions of chemical and organic fertilizers (Daily *et al.*, 1997; Matson *et al.*, 1997).

Pollination

Animal pollinators are essential for approximately 35% of global crop production, and 60–90% of all plant species are pollinator-dependent (Klein *et al.*, 2007). Bees are recognized as the taxon providing most pollination services, yet other taxa – including birds, bats, thrips, butterflies and moths, flies, wasps, and beetles – also pollinate some of the world's most important food crops (Nabhan and Buchmann, 1997). Pollination is necessary for sexual reproduction in many crops, including fruits, vegetables, nuts, and seeds (Klein *et al.*, 2007) as well as many wild plants known to contribute calories and micronutrients to human diets (Sundriyal and Sundriyal, 2004). There are also many globally important crops that are pollinated passively or by wind, including cereals, sugarcane, and grasses (Klein *et al.*, 2007).

Overall, pollinators play a significant role in the world's food systems and agricultural economies. The estimated value of insect-pollinated crops in the United States ranged from US $18–27 billion in 2003. If calculations include secondary products, such as beef and milk from cattle fed alfalfa, the estimated value more than doubles (Mader *et al.*, 2011). Although honey bees (*Apis* spp.) are the most important commercially managed pollinator, native and wild bee species also make significant contributions. Approximately 15% of the value associated with pollination services comes from native bees and other animals living in farmlands and adjacent natural habitat (Mader *et al.*, 2011). Both agricultural management and landscape configuration are important in determining availability and distribution of pollination services. Some wild (native) pollinators nest within fields, including ground-nesting bees, or disperse from nearby unmanaged habitats to pollinate crops (Ricketts *et al.*, 2004). Conserving wild pollinators in unmanaged or restored natural habitats adjacent to agricultural fields can improve pollination levels and stability, which can support increases in agricultural yields (Klein *et al.*, 2003).

The potential contributions of native pollinators have received a great deal of recent attention due to global declines in managed honey bee colonies (National Academies, 2006). Declines in honey bee abundance, driven by establishment of parasitic mites (e.g., *Varroa destructor)*, hive pests, and social factors such as aging beekeeper populations, have resulted in pollination shortages in some areas (Klein *et al.*, 2007). This has caused increased prices for honey bee rental and created concern about pollination shortfalls, such as those seen in California almonds (National Academies, 2006). These factors have heightened interest in the role of native pollinators to help assure availability and stability of crop pollination services. Recommendations for managing pollinator-friendly landscapes include maintaining areas of natural and semi-natural perennial habitat (e.g., grass and woodlands, forests,

old fields, and hedgerows) to provide ample floral and nesting resources available throughout the year (Kremen *et al.*, 2007; Mader *et al.*, 2011).

Pest control

Pest damage is a major limiting factor for global food production. Animal pests destroy 8–15% of global wheat, rice, maize, potato, soybean, and cotton production (Oerke, 2005) and cause more than US$30 billion in damage in the United States each year (Pimentel *et al.*, 2005). However, despite dramatic increases in pesticide application, damage levels remained roughly unchanged during the four decades following the escalation of pesticide use after World War II (Pimentel *et al.*, 1992; Oerke, 2005). Pesticides have even precipitated pest outbreaks. For instance, Southeast Asian rice fields were devastated by the brown planthopper (*Nilaparvata lugens*) after excessive pesticide application caused the pest to evolve resistance while its predators continued to suffer high mortality (Kenmore *et al.*, 1984). In Indonesia, planthopper outbreaks abated once many pesticides were banned (Naylor and Ehrlich, 1997). Instead, farmers adopted an integrated pest management approach in which natural pest predators were fostered, and pesticides were used only after damage exceeded critical economic thresholds.

The idea that farmers can harness nature to provide pest control benefits is not new. As early as AD 304, Chinese farmers created and maintained citrus ant (*Oecophylla smaragdina*) nests in their orchards to control pest outbreaks (Huang and Pei, 1987). Centuries later, in 1888, the modern concept of classic biological control emerged, again in citrus orchards, when introduced vedalia beetles (*Rodolia cardinalis*) caused the near complete collapse of cottony-cushion scale (*Icerya purchasi*) pests in California (Caltagirone and Doutt, 1989). Since then it has become widely recognized that adjusting agricultural practices to benefit pest predators can provide a valuable pest control strategy with significant benefit to farmers.

Strategies for enhancing pest control services to agriculture may require understanding predator ecology to ensure that pest predators have suitable food and habitat resources throughout their life cycles (Landis *et al.*, 2000). Plants that provide floral or nectar resources can be used to sustain predators and parasitoids. Sweet alyssum (*Lobularia maritima*) has proven especially effective for bolstering syrphid fly abundances in California (Tillman *et al.*, 2012). Predator populations can also be enhanced indirectly through agricultural practices that increase nonpest prey, for example, by applying mulch or intercropping (Riechert and Bishop, 1990; Bugg *et al.*, 1991). Small patches of native vegetation on and around farms can provide these species with food resources and overwintering habitat (Landis *et al.*, 2000; Tillman *et al.*, 2012). Emerging evidence suggests that conservation activities at a landscape scale can also benefit farmers. For example, conserving natural habitat surrounding farms increases predators and often enhances pest control services (Thies and Tscharntke, 1999; Bianchi *et al.*, 2006; Chaplin-Kramer *et al.*, 2011b; Karp *et al.*, 2013). These examples represent but a few of many techniques that have emerged for controlling crop pests with native predators, many of which are readily accessible to farmers through government, university, and agency extension programs.

Hydrologic services – water flow regulation and water purification

Agricultural production relies on a host of water-related ecosystem services, ranging from water supply (quantity), to purification (quality), and flood protection (Brauman *et al.*, 2007). Globally, agroecosystems are a major consumer of groundwater and surface water, accounting for approximately 70% of freshwater use worldwide (UN Water, 2013). Agricultural water use may be as high as 90% of total withdraws in fast-growing economies (UN Water, 2013) or arid environments (USDA ERS, 2013). Irrigation is considered a consumptive water use, in that water is not directly returned to rivers and streams. Much of this water eventually returns to the atmosphere through evaporation and plant transpiration (e.g., the process of water moving through plant tissues and evaporating through leaves, stems, and flowers), particularly in thirsty crops, such as alfalfa and cotton.

The majority of prime land for rainfed cultivation is already in use and development of irrigated land has contributed substantially to production gains. A prime example is in India, where the growth of irrigated rice and wheat on the semiarid plains of Punjab has substantially boosted food production over the past several decades (Matson *et al.*, 1997). Globally, approximately 40% of crop production is supported by irrigated agricultural lands, which account for 20% of all agricultural areas (UN Water, 2013). Scientists project that continued increases in agricultural production would require sustained or increased supply of irrigation water (Matson *et al.*, 1997).

Ecosystems do not create water; however, they can modify the amount of water moving through the landscape. These modifications result from ecosystem influence on the hydrologic cycle, including local climate, water use by plants, and modification of ground surfaces that alter infiltration and flow patterns (Brauman *et al.*, 2007). The amount of water stored in watersheds, or discharged above and below ground, influences water supply and availability to downstream users. The understanding of how water availability changes with land use and land cover change is elementary (Brauman *et al.*, 2007). Planting of forests and trees – native or introduced – can either increase or decrease evapotranspiration and downstream water availability, depending on the context. In one study, analysis of paired catchment experiments found that stream flows were reduced 45% on an average when grasslands were converted to forests (Farley *et al.*, 2005). Other studies from the Amazon basin illustrate that evapotranspiration from a pasture can be up to 24% less than a nearby forest (Von Randow *et al.*, 2004). Vegetation can also be selected to support management goals based on water requirements. For example, Australian studies describe use of plants such as lucerne (*Medicago sativa*), eucalyptus trees (*Eucalyptus* spp.), and saltbush (*Atriplex* spp.), which are thought to mitigate potential crop damages in areas where rising water tables bring saline water into root zones by lowering water tables through high transpiration rates (Heuperman *et al.*, 2002).

Water purification depends on filtration and absorption of particles and contaminants by clay, silt, and sand particles in soil as well as living organisms in soil and water. Agricultural production depends on water quality to maintain productive capacity, but there are a number of threats and challenges the

continued provision of clean water. Irrigated farmlands in arid and semiarid regions are experiencing degradation due to salinization and waterlogging (Matson *et al.*, 1997).

Maintaining water quality for agriculture and other uses is increasingly thought to require maintaining buffers of vegetation with intact groundcover and root systems throughout the watershed. Vegetation, microbes, and stabilized soils can remove pollutants from overland flow and from groundwater by physically trapping water and sediments, by adhering to contaminants, by reducing water speed to enhance infiltration, by biochemical transformation of nutrients and contaminants, and by absorbing water and nutrients from the root zone (Naiman and Décamps, 1997). Vegetated riparian buffer zones in particular perform critical functions to support water quality.

Genetic resources provide a pool of raw material necessary to support the process of natural selection and produce evolutionary adaptations in unmanaged ecosystems. In agroecosystems, crop and animal breeders draw on genetic diversity using traditional breeding and biotechnology to artificially select and perpetuate desirable traits (Zhang *et al.*, 2007). A broad portfolio of genetic resources increases the likelihood of maintaining production, particularly as environmental pressures such as climate, pests, and disease fluctuate. Production stability comes through an array of genotypes, each with different characteristics of disease resistance, tolerance for environmental extremes, and nutrient use (Esquinas-Alcázar, 2005). Different genotypes, or cultivars, are required for plants in orchard systems and hybrid seed production to set fruit or seed (Free, 1993; Delaplane and Mayer, 2000). The benefits of genetic variation at the species level include enhanced biomass production, reduced loss to pests and diseases, and more efficient use of available nutrients (Tilman, 1999).

Crop production is supported by genetic resources from two important sources. First are 'landraces,' the varieties of crops and livestock that have been cultivated and selected by farmers over many generations practicing traditional agriculture (Shand, 1997). Second are closely related species that survive in the wild, known as crop 'wild relatives.' Areas with high concentrations of landraces and wild relatives are considered centers of crop genetic diversity (Shand, 1997). These centers are critical, as many important crops could not maintain commercial production without periodic infusions of genetic resources from wild relatives (de Groot *et al.*, 2002).

The consequences of losing genetic resources in a crop system can be severe. The Irish potato famine in the 1830s is one such example. The crop failure can be attributed in part to a very limited number of genetic strains of potatoes in Ireland, which made the crop particularly susceptible to potato blight fungus (Hawtin, 2000). Reintroducing disease-resistant varieties from Latin America, where the potato originated, helped to resolve the problem. Recent reviews of crop genetic resources highlight that increases in human population size, ecological degradation in farmlands, and globalization have contributed to a dramatic reduction of crop diversity worldwide. Approximately 150 species now comprise the world's most important food crops and most human diets are dominated by no more than 12 plant species (Esquinas-Alcázar, 2005). Loss of crop genetic diversity is of great concern because it reduces the pool of genetic material available for natural selection and artificial selection by farmers and plant breeders, thereby increasing the vulnerability of crops to sudden environmental changes (Esquinas-Alcázar, 2005).

Disservices to Agriculture Detract from Agricultural Productivity

Disservices to agriculture result from the ecological processes or relationships that detract from agricultural productivity. Crop pests, including seed eaters, herbivores, frugivores, and pathogens (e.g., insects, fungi, bacteria, and viruses), can result in reduced productivity, or total crop loss in worst case scenarios (Zhang *et al.*, 2007). Weeds and other noncrop plants can reduce agricultural productivity through competition for resources. At the field scale, weeds compete with crops for sunlight, water, and soil nutrients and may limit crop growth and productivity by limiting access to these critical resources (Welbank, 1963). Within fields, plants may exhibit allelopathy (biochemical inhibition of competitors), such as the toxins exuded by some plant roots that can decrease crop growth (Weston and Duke, 2003).

Resource competition that potentially detracts from agricultural yields can also take place at larger scales. Competition for pollination from flowering weeds and other noncrop plants beyond agricultural fields can reduce crop yields (Free, 1993). Water used by other plants, such as trees that reduce aquifer recharge, can reduce water available to support agricultural production by diminishing an important source of irrigation water (Zhang *et al.*, 2007).

Food safety concerns related to pathogen outbreaks are other potential detractors from agricultural productivity. Since the 1990s these concerns have gained some prominence in highly productive regions, such as the Salinas Valley of California (the 'salad bowl of America'), which experienced *Escherichia coli* contamination of leafy greens. The unfortunate consequence has been broad-scale removal of riparian habitat to minimize wildlife intrusion into crop fields. Wildlife was posited to spread harmful bacteria, although whether it constitutes a significant food safety risk remains unclear. Nevertheless, over a 5-year period following an *E. coli* O157:H7 outbreak in spinach, 13.3% of remaining riparian habitat was removed from the Salinas Valley (Gennet *et al.*, 2013). This habitat removal may result in degradation or loss of the ecosystem services typically provided by riparian areas.

It is important to note that disservices from agriculture can also affect the productivity and environmental impacts of farming systems through multiple feedbacks. For instance, when habitat for natural enemies is removed, pest outbreaks can result in crop damage or loss, resulting in reduced productivity and potentially increased use of pesticides, which may be accompanied by further detrimental effects. Similarly, when riparian habitat is degraded or removed, the hydrologic services of water flow regulation and water purification services can be diminished or lost (**Figure 2**).

Managing Ecosystem Services in Agricultural Landscapes

Different ecosystem services are mediated and delivered at different scales, ranging from individual farm plots to entire

watersheds or regions (Zhang *et al.*, 2007). Accordingly, efforts to maintain or enhance ecosystem services in farming landscapes may require deliberate management of different areas and scales, including cultivated areas within farms, noncultivated areas within farms, and broader landscapes (well beyond farm boundaries) that comprise both cultivated and noncultivated areas.

Management of cultivated fields often focuses on ecosystem services that have a direct influence on farm productivity; farmers have a direct interest in managing services, including pollination, pest control, soil fertility and nutrient cycling, soil retention, water purification, and water flow regulation. On-farm practices that target water conservation, including moisture from rainfall that is stored in the soil profile, may help to offset water shortages during dry seasons or droughts (Rost *et al.*, 2009). Mulching or modification of field tillage practices can reduce evaporation of soil water by 30–50%. In addition, farmers can harvest rainwater by installing microtopographic features in their fields (e.g., small bunds or pits) as well as ponds, dykes, or other infrastructure, enabling recovery of up to 50% of water normally lost in the system (Rost *et al.*, 2009; Power, 2010).

Management of noncultivated areas of farms may support both ecosystem services of benefit both to farmers themselves and to the broader public. Studies of smallholder farms have documented the benefits of planting trees in noncultivated areas, in both temperate and tropical regions, including Nepal (Carter and Gilmour, 1989) and Costa Rica (Casasola *et al.*, 2007). Increasing tree cover is associated with enhanced diversity and richness of mobile organisms – such as birds, bats, and butterflies (Harvey *et al.*, 2006) – soil retention (Carter and Gilmour, 1989), and carbon sequestration (Montagnini and Nair, 2004). In the case of management that supports ecosystem services, which provide public benefits but does not directly support farm productivity (e.g., carbon sequestration needed to support climate regulation), farmers may have less incentive to implement management practices. To stimulate provision of public benefits, policies and programs may be needed to offset the costs of management investments or create financial incentives for using new management practices (Garbach *et al.*, 2012).

Broader landscape management to support ecosystem services requires to understand the ways in which ecosystem processes take place across multiple parcels of land (including movement of biotic and abiotic components, such as organisms, water, and nutrients). Pollination illustrates the importance of broader landscape management, highlighting that mobile organisms respond to resources both within and beyond cultivated fields. Studies in California suggest that pollination by native bees was higher in farms near greater proportions of natural habitat (no significant relationship was found between pollination and farm type, insecticide usage, field size, or honeybee abundance) (Kremen *et al.*, 2004). There is some evidence that multiple farmers practicing diversified farming – using practices focused on maintaining and enhancing biodiversity of flora and fauna within and across fields – across a region can result in greater provision of ecosystem services than simply the sum of their individual management actions (Gabriel *et al.*, 2010).

Considerations for Managing Ecosystem Services

Managing ecosystem services requires building an in-depth understanding of the species, functional groups, and ecological processes through which services are provided (Kremen, 2005). **Table 2** highlights some of the key organisms, guilds, and communities that are the biological mediators of ecosystem services and disservices to agriculture. Their biological activities affect the provision of ecosystem services at the field, farm, landscape, and regional-to-global scales. For example, at the field scale, services of soil structure and fertility enhancement (including the processes of soil formation, development of structure, and nutrient cycling) are provided by microbes, invertebrates, and nitrogen-fixing plants. Thus, field-scale management may focus on practices such as incorporating nitrogen-fixing plants into crop rotations and planning the timing and depth of tillage to minimize impacts on beneficial invertebrates. At the farm scale, soil-related ecosystem services may also be influenced by levels and types of vegetative cover; thus, farm-scale management may focus on the total area, type, and timing of harvest (if any) of vegetation, including both cultivated and noncultivated areas (**Table 2**).

Measuring Ecosystem Services and Evaluating Service Providers

There is a great deal of interest in methods used to measure provision of ecosystem services. One method is to evaluate the presence or abundance of organisms believed to provide ecosystem services. A second method is to measure the delivery of the service themselves (Kremen and Ostfeld, 2005). For instance, in order to measure pollination in a California squash field, the first method would focus on the abundance and distribution of key pollinators, such as native squash bees (*Peponapis pruinosa*) and other insects. Alternatively, the second method would evaluate whether a squash crop was sufficiently pollinated. These two methods are complementary and may be used together to build a comprehensive understanding of ecosystem service delivery. Counting ecosystem service providers can provide insight into the likelihood of an ecosystem service being available. In contrast, measuring the outcomes (e.g., pollination metrics, such as seed set or pollination deficit) can help to verify delivery of a service but does not provide much information about the organisms providing the service. A comprehensive approach to understanding and measuring ecosystem services includes understanding key ecosystem service providers (e.g., organisms, guilds, and communities), factors influencing the ability of providers to deliver services of interest, and measuring spatial and temporal scales over which providers operate and ecosystem services are available (Kremen and Ostfeld, 2005).

The relationships between biodiversity and ecosystem function are also important for understanding provision of ecosystem services (Altieri, 1995; Hooper *et al.*, 2005; Tscharntke *et al.*, 2005). In general, species richness – measured as the number of species in a given area – is associated with enhanced ecosystem services (Balvanera *et al.*, 2006). Similarly, biodiversity loss is associated with diminished

Table 2 Ecosystem services and disservices to agriculture, the scales over which they are typically provided, and organism, guilds, and communities that provide them

	Organisms, guilds, and communities that provide services at the following scales:			
	Field	*Farm*	*Landscape*	*Region/globe*
Services to agriculture				
Genetic resources	Diversity within a single crop; genotypes help to provide pest and disease resistance	Diversity across multiple crops; rotations help to provide pest and disease resistance	Landrace varieties, wild relatives of crops; can be used to infuse crops with genetic diversity	Landrace varieties, wild relatives of crops; can be used to infuse crops with genetic diversity
Hydrologic services: Water flow regulation, water purification	Vegetation within cultivated areas	Vegetation around water sources, drains, and ponds	Vegetation cover in watershed; riparian communities	Vegetation cover in watersheds; riparian communities
Pest control	Predators, parasites (animals and insects, including vertebrates, invertebrates, and parasitoids)	Predators, parasites (animals and insects, including vertebrates, invertebrates, and parasitoids)	Predators, parasites (animals and insects including vertebrates, invertebrates, and parasitoids)	–
Weed control	Predators, competitors (herbivores, seed predators, and other competitors that limit plants and fungi)	Predators, competitors (herbivores, seed predators, and other competitors that limit plants and fungi)	Predators, competitors (herbivores, seed predators, and other competitors that limit plants and fungi)	–
Pollination	Pollinators: primarily bees but also bats, thrips, butterflies and moths, flies, wasps, beetles, and birds (note: some crops are wind-pollinated)	Pollinators: primarily bees but also bats, thrips, butterflies, and moths, flies, wasps, beetles, and birds (note: some crops are wind-pollinated)	Pollinators: primarily bees but also bats, thrips, butterflies and moths, flies, wasps, beetles, and birds (note: some crops are wind-pollinated)	–
Soil structure and fertility (including processes of soil formation, development of structure, nutrient cycling supporting fertility)	Microbes, micro and macro invertebrates, nitrogen-fixing plants	Vegetative cover	Vegetative cover	–
Erosion protection	Cover crops and perennial crops	Cover crops and perennial crops	Riparian vegetation; vegetative cover on steep areas, thin soils; floodplains	Riparian vegetation; vegetative cover on steep areas, thin soils; floodplains
Disservices to agriculture				
Pest damage and pathogen outbreaks	Insects, snails, birds, mammals, fungi, bacteria, viruses, and weeds	Insects, snails, birds, mammals, fungi, bacteria, viruses, and weeds	Insects, snails, birds, mammals, fungi, bacteria, viruses, and rangeland weeds	–
Competition for water	Weeds	Vegetation near drainage ditches	Vegetation in watersheds	Vegetation in watersheds
Competition for pollination	Flowering weeds	Flowering weeds	Flowering plants in watershed

provision of ecosystem services, often due to reduced efficiency of resource capture and use in ecological communities, diminished biomass production, and diminished rates of nutrient decomposition and recycling (Cardinale *et al*., 2012). In addition to biodiversity, ecosystem function is influenced by the identity, density, biomass, and interactions of species within a community (Kremen and Ostfeld, 2005). These attributes can aggregate at different levels (e.g., field, farm, and landscape scales). Thus, it is important to consider how ecological attributes may vary over space and time, as this can influence when and where ecosystem services are available.

Many ecological studies aim to understand which populations, species, functional groups, guilds, food webs, and habitat types produce key services. One method to do so is a functional inventory, which includes identifying and describing the focal ecosystem service providers in a landscape and quantifying their contributions (Kremen and Ostfeld, 2005). A functional inventory is most relevant at the scale of the focal ecosystem service. Thus, evaluating disease resistance in crops may require a functional inventory at the genetic level, (Zhu *et al*., 2000) whereas evaluating biological control of pests may require an inventory at the

level of a population or food web (Kruess and Tscharntke, 1994).

Functional Differences

A second method to build understanding of ecosystem service providers is evaluating functional attribute diversity (Kremen and Ostfeld, 2005). This method describes differences within the guild, functional group, or community that provides each service. A commonly used metric is ecological distance, which describes differences in morphology, ecology, or behavior of the organisms (Laliberté and Legendre, 2010; Walker *et al.*, 1999) that provide ecosystem services. Characteristics that determine how an organism performs key functions are often used for measuring ecological distance, such as root depth of plants (potential determinant of water flow regulation), timing of emergence and senescence (primary production and nutrient cycling), or pollinator's tongue length (pollination).

Response to Disturbance

Comprehensive evaluation of the abundance of ecosystem services providers, and broader patterns of ecosystem services availability, can build a solid foundation for investigating potential influence of disturbance. For example, what happens when species that provide key services are lost? Sometimes ecosystem services are resilient to disturbance and loss. If remaining species can compensate for the species that are removed or have become extinct, ecosystem services may also be maintained rather than diminished. This compensation effect can happen in several ways.

First, compensation can occur through response diversity, described as the diversity of responses to change shown among species contributing to the same ecosystem functions and services disturbance (Elmqvist *et al.*, 2003). Second, it can occur through functional compensation, which occurs when efficiencies of individual ecosystem service providers shift in response to changing community composition. Third, compensation may also happen through the portfolio effect. Just as having a diverse investment portfolio may buffer an investor against fluctuations in individual investments, a diverse biological community is more likely to contain some species that can persist through disturbances (Tilman *et al.*, 1998).

Promoting Synergies between Yield and Ecosystem Services

Recent global estimates project the need to double world food production by 2050 (World Bank, 2008a; The Royal Society, 2009; Godfray *et al.*, 2010). At the same time, there is a growing consensus that increased food production must not come at the expense of diminishing key ecosystem services, such as carbon sequestration, water flow regulation, and water purification. Additionally, the prospect of clearing additional land for agriculture is unappealing, as most of the remaining potentially arable land on the Earth is covered by tropical rainforest; agricultural expansion in these areas would come at a steep cost to biodiversity and the delivery of services from biodiversity-rich rainforests (Ramankutty and Rhemtulla, 2012). Therefore, existing farmlands are being called on to simultaneously increase crop yields and provision of ecosystem services. This call for multifunctional agricultural landscapes can be summarized as agroecosystems in which productivity and ecological integrity are complementary outcomes, rather than opposing objectives.

Agroecology is a scientific subdiscipline and farming approach intended to do precisely this by applying ecological concepts and principles to the design and management of sustainable farming systems (Altieri, 1995). Agroecology emphasizes understanding the ecology of crop, livestock, and other species in a farming system as well as the mechanisms that govern their functions. It highlights the role of human managers in maintaining and enhancing desirable functions and related ecosystem services to optimize use of water, energy, nutrients, and genetic resources (Altieri, 1995; Gliessman *et al.*, 1998). In doing so, the practice of agroecology often seeks to intensify production systems – that is, to deliver greater yields per unit of land, water, or other inputs used – in a way that is based on and, in turn, maintains healthy systems of soil, water, and biodiversity.

There is considerable evidence that systems of agroecological intensification can increase yields relative to prevailing farmer practices in many parts of the world (e.g., Pretty *et al.*, 2006). A recent quantitative review investigated whether agroecological intensification systems tend to deliver yield and ecosystem service benefits simultaneously (Garbach *et al.*, in press). Here the authors summarize results for two illustrative systems of agroecological intensification: conservation agriculture and the system of rice intensification.

Conservation agriculture is an agroecological intensification system that aims to increase productivity and sustainability of soil resources through three main practices: (1) minimal soil disturbance, (2) permanent soil cover, and (3) crop rotations (Kassam *et al.*, 2009). Development agencies, such as the Food and Agriculture Organization of the United Nations, have promoted this system due to its potential applications in farms of diverse sizes and crop systems (FAO, 2011).

Field studies of conservation agriculture report benefits in soil structure, nutrient cycling, erosion protection, and animal biodiversity relative to conventional soil tillage (Milder *et al.*, 2012). However, inconsistent results have been reported for key services, such as pest control, which was found to be diminished in some field studies due to increased pests harbored by crop residues (Van den Putte *et al.*, 2010). Other field studies have reported increased pest control associated with maintaining soil cover (e.g., mulching and retaining plant residues on soil surfaces) and increased species richness and population density of beneficial insects, such as predatory crickets, beetles, bugs, ants, and spiders (Jaipal *et al.*, 2005).

Synergistic outcomes in conservation agriculture – enhanced yield and ecosystem services – were reported in approximately 40% of comparisons (17 of 43 total quantitative comparisons with conventional cultivation, reported in 16 studies, Garbach *et al.*, in press) (**Figure 3**). However, conservation agriculture studies have also reported trade-offs, such as enhanced yield despite diminished weed control services (Haggblade and Tembo, 2003) and diminished yield but

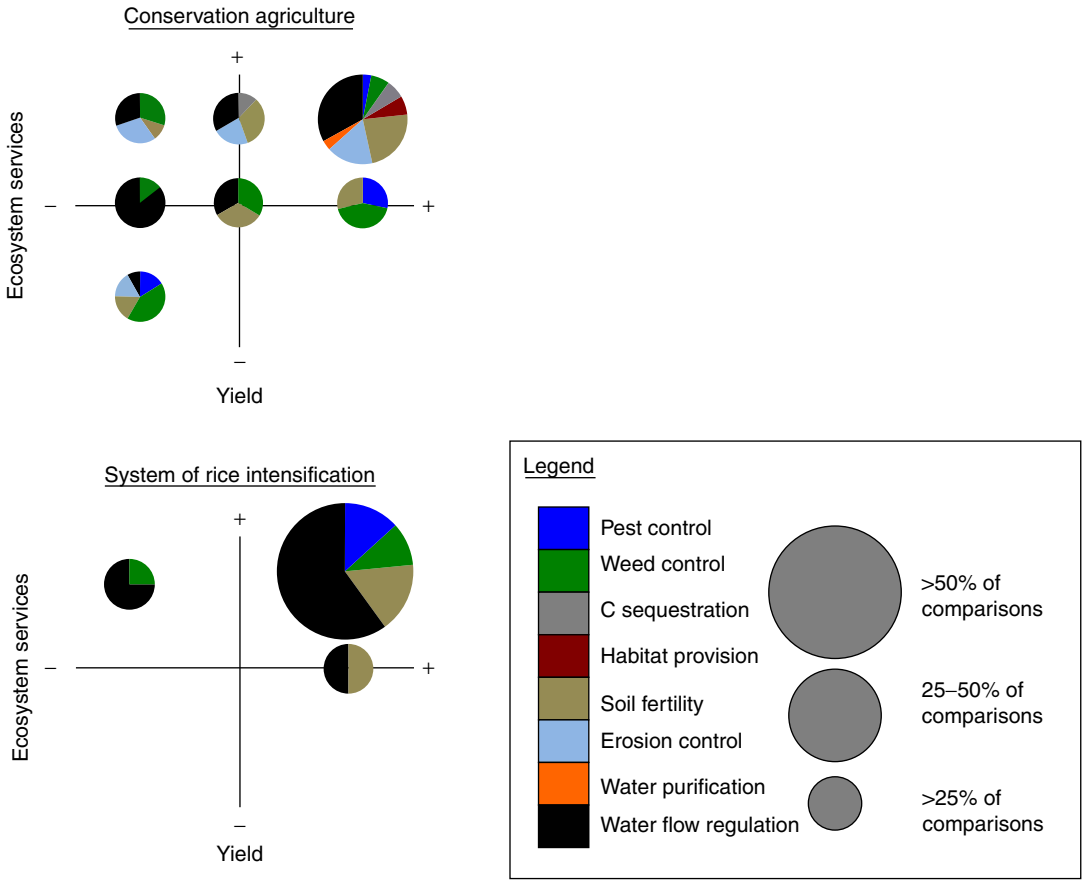

Figure 3 Synergies and trade-offs between ecosystem services and yield in conservation agriculture and system of rice intensification. Bubble location indicates the specific combination of outcomes for ecosystem services (Y-axis: enhanced, upper quadrants; diminished, lower quadrants) and yield (X-axis: enhanced, right quadrants; diminished, left quadrants) relative to comparison systems. Bubbles located on the axis indicate no significant difference from the comparison system. Bubble size indicates the percent of reviewed comparisons reporting each combination of yield and AEI outcomes: large bubbles indicate >50% of comparisons; medium bubbles indicate 25–50% of comparisons; and small bubbles indicate <25% of comparisons. The ecosystem services evaluated are represented by colored charts in each bubble and represented as the percentage of comparisons in which the ecosystem service was measured. Adapted from Garbach, K., Milder, J.C., DeClerck, F., *et al.*, in press. Closing yield gaps and nature gaps: Multi-functionality in five systems of agroecological intensification. Proceedings of the National Academy of Sciences-Plus.

enhanced soil structure and erosion control (Araya *et al.*, 2011) (7% of comparisons, **Figure 3**). A small number of studies have reported both diminished yield and ecosystem service (6% of comparisons, **Figure 3**). Diminished yield in conservation agriculture was often associated with a decrease in weed control (Narain and Kumar, 2005) and pest control services (Van den Putte *et al.*, 2010).

The system of rice intensification has received a great deal of recent attention as an agroecological intensification system developed specifically for a staple grain. This approach to irrigated rice cultivation includes six key practices: transplanting young seedlings; low seedling density with shallow root placement; wide plant spacing; intermittent application of water (vs. continuous flooding); frequent weeding; and incorporation of organic matter into the soil, possibly complemented by synthetic fertilizer (Africare, Oxfam America, WWF-ICRISAT, 2010).

Field studies report considerable evidence for synergies between yield and ecosystem services in the system of rice intensification, particularly water flow regulation. Enhancement of both yield and ecosystem services were reported in 87% of comparisons (39 of 45 quantitative comparisons reported in 15 studies, Garbach *et al.*, in press) (**Figure 3**). Most studies compared the system of rice intensification to the predominant unintensified farmer practices in the study area. Thus, the results suggest that the system of rice intensification can significantly improve productivity and ecosystem service delivery relative to current practices in many regions. However, the relative benefits of the system of rice intensification compared with regionally specific best management practices in conventional rice farming are less clear (McDonald *et al.*, 2006).

Landscape Context

From above, agricultural landscapes often resemble a patchwork of rural villages, natural and seminatural habitat, and farms cultivating a diverse array of crops. 'Natural habitat' in this context describes the full range of natural, seminatural, and weedy vegetation types that tend to be present in

agricultural areas. However, over the past decades in many parts of the world, remnants of natural habitat have begun disappearing, replaced by vast fields of industrial agriculture (Perfecto *et al.*, 2009). This physical restructuring of agricultural landscapes has resulted in dramatic changes in many critical ecosystem services.

Ecological processes often occur at scales larger than individual farms, making the composition of the broader agricultural landscape an essential determinant of ecosystem service provision. Natural habitat can provide many benefits to farmers and the public (Kremen and Miles, 2012). Benefits include harvestable goods, such as fuelwood, medicinal plants, and bushmeat, as well as genetic resources provided by crop wild relatives. Natural habitat can provide recreational opportunities and has been found to support mental health in some case studies (Bratman *et al.*, 2012).

Ensuring that agricultural systems realize diverse benefits requires looking beyond on-farm practices and managing the broader landscape. Here the authors focus on examples of landscape management for two animal-mediated ecosystem services: pollination and pest control. Many other ecosystem services, including water purification, genetic resources, and soil structure and fertility enhancement, also require landscape management. Animal-mediated services, however, are among the most severely affected by landscape simplification, and landscape-level effects have been well documented.

When natural habitat is removed for agriculture, beneficial pollinators and predators of insect pests often decline in abundance, whereas pests increase, which may precipitate lower yields for farmers (Philpott *et al.*, 2008; Karp *et al.*, 2011; Melo *et al.*, 2013). The amount of natural habitat required to sustain pest control and pollination services is often a product of the home range sizes of the predator and pollinator species that provide these services, an attribute that can vary considerably among species. The relevant management scale for farmers depends on both the focal ecosystem service and on the attributes of its animal providers. Fortunately, the past decades have seen a surge of research documenting the role of landscape structure and composition in sustaining pollinators and pest control providers.

Pollination

Although managed honey bees (*Apis mellifera*) provide most pollination globally, native insects are often more effective pollinators and provide complementary pollination benefits (Garibaldi *et al.*, 2013). Further, native insects enhance pollination resilience, especially as honey bee colonies continue to collapse (Winfree and Kremen, 2009). Retaining a diverse pollinator community is thus increasingly recognized as an essential component of any sustainable food system.

Unsurprisingly, native pollinators rely on native habitat. Many species center their foraging activity around the nest, often located in patches of habitat embedded in agricultural landscapes (Lonsdorf *et al.*, 2009; Jha and Kremen, 2013). Pollinator activity matches pollinator foraging ranges, and pollination is thus consistently higher at the edges of crop fields near native habitat than in the interior of large crop monocultures (Kremen *et al.*, 2004; Ricketts *et al.*, 2004, 2008; Klein *et al.*, 2012). As large fields of a single crop variety replace more diversified farms, the total length of time during which crop species are flowering becomes shorter. As a result, pollinators may become increasingly dependent on the wild plants that flower throughout the year in noncropped areas (Mandelik *et al.*, 2012). Pollination services are thus not only higher but also more stable at field edges than in the interior (Garibaldi *et al.*, 2011).

Although pollination services may vary from crop to crop, pollinator to pollinator, and region to region, the positive influence of natural habitat on pollinator activity has proven remarkably consistent across many studies (Ricketts *et al.*, 2008). This consistency has allowed researchers to create spatial pollination models that estimate pollination provision on the farm based on the composition of the surrounding landscape (Lonsdorf *et al.*, 2009). For instance, the InVEST, the ecosystem service modeling platform operated by the Natural Capital Project, allows land managers to predict the pollination consequences of their land-use decisions and manage land assets accordingly.

Pest Control

Not all crops are animal pollinated, but every crop suffers pest damage. The shift from diversified, agricultural landscapes with patches of natural habitat to large monocultures that lack natural habitat has likely brought with it more severe pest outbreaks. High vegetation diversity ensures that specialist pests do not enjoy vast food resources (Matson *et al.*, 1997). Further, because not all crops and vegetation in natural habitat is palatable to pests, complex landscapes may inhibit pest movements and cause more localized outbreaks (Avelino *et al.*, 2012). However, natural habitat can sometimes provide pests with resources vital for completing their lifecycles and thus facilitate outbreaks (Chaplin-Kramer *et al.*, 2011b). For example, because aphids sequester chemicals in wild mustards (*Brassica nigra*) as antipredator defenses, the proximity of natural habitat with high mustard density may function to increase the density of aphids in nearby crop fields (Chaplin-Kramer *et al.*, 2011a).

Another critical consideration, however, is the predators of crop pests. Predators rely on natural habitat for essential activities, including breeding, roosting, foraging, and hibernating (Landis *et al.*, 2000; Jirinec *et al.*, 2011). Predator abundance and diversity thus regularly decline as agricultural landscapes shift from complex mosaics of natural habitat and cropland to simplified monocultures (Bianchi *et al.*, 2006; Chaplin-Kramer *et al.*, 2011b). Although diverse predator communities are not always more effective at providing pest control because predators sometimes consume each other (Vance-Chalcraft *et al.*, 2007), most studies report that more predator diversity translates to more effective pest control (Bianchi *et al.*, 2006; Letourneau *et al.*, 2009; Chaplin-Kramer *et al.*, 2011b).

An increasing number of studies have documented increased pest consumption in complex versus simple landscapes (Thies and Tscharntke, 1999; Gardiner *et al.*, 2009; Chaplin-Kramer and Kremen, 2013; Karp *et al.*, 2013). Fewer studies, however, have traced the benefit of maintaining natural habitat

all the way to crop yields and profits, but some have reported positive effects (Thies and Tscharntke, 1999; Karp *et al.*, 2013). Like pollination, the relevant scale for pest management can vary from predator to predator and from pest to pest, such that distant areas may determine the abundance of highly mobile animals (Werling and Gratton, 2010). Simply focusing on local agricultural practices may be ineffective. Because predator communities often collapse after harvest, a stream of colonizers from adjacent natural habitat may be required to replenish the predator community in the following year.

Landscape Effects on Agriculture: A Costa Rican Case Study

Tropical rainforest provides an array of ecosystem services, including water purification, water flow regulation (e.g., supporting hydropower production), carbon sequestration, and cultural services such as ecotourism. Recognizing this, in the mid-1990s the Costa Rican government created the first national payment for ecosystem services (PES) scheme, in which landowners were paid to maintain rainforest on their private lands (Sánchez-Azofeifa *et al.*, 2007). For farmers, the program provided the dual benefit of monetary compensation for uncultivated lands and continued provision of critical ecosystem services.

The canton of Coto Brus in Southern Costa Rica has been studied as a model system for how strategic conservation efforts influence agricultural production. Unlike many other parts of the country that now host vast expanses of pineapple, oil palm, or banana, Coto Brus still exists as a patchwork of coffee plantations, pasture, small rural villages, and tropical wet forest, perhaps a result of its hilly terrain (Mendenhall *et al.*, 2011). This complex configuration supports a remarkable concentration of biodiversity, often at par with native forest (Daily *et al.*, 2001; Mendenhall *et al.*, 2013). Coffee, the most extensively cultivated crop in the region, benefits from this biodiversity. Although coffee can self-pollinate, animal pollination increases yields, sometimes by more than 50% (Ricketts *et al.*, 2004). Because wild bees rely on rainforest habitat, coffee plants located near rainforest enjoy significantly higher pollination than sites in the middle of extensive plantations. Higher pollination translates to higher yields, better coffee quality, and increased profits. One study found that yields increased by 20% and misshaped 'peaberries' decreased by 27% within 1 km distance of two forest patches (Ricketts *et al.*, 2004). These benefits translated into a significant economic gain, approximately US$60 000 per year for a single coffee plantation.

Costa Rican coffee plantations also enjoy pest control benefits from forest patches. The coffee berry borer beetle (*Hypothenemus hampeii*), coffee's most damaging insect pest, arrived in Costa Rica in 2000 and the canton of Coto Brus in 2005 (Staver *et al.*, 2001). Not more than 5 years later, native birds had already expanded their diets to include the pest and began reducing infestation severity by half (Karp *et al.*, 2013). Like wild bees, many of the pest-eating birds rely on forest habitat, and pest control provision is higher on farms with more forest cover (Karp *et al.*, 2013). Small, unprotected forest patches embedded in coffee plantations provided the most benefits. Forest patches smaller than 1 ha area secured approximately 50% of the total pest control benefits across the Coto Brus valley (Figure 4).

Policies and Programs to Conserve and Enhance Ecosystem Services in Agricultural Landscapes

Growing interest in the management of ecosystem services has been matched, in recent years, by a proliferation of policy and programmatic strategies to promote the conservation or enhancement of these services in agricultural landscapes. Traditionally, environmental management policies were often described in terms of a dichotomy between regulatory instruments ('command and control' requirements put forth by governments) and market-based instruments focused on shifting incentives and price signals for farmers, businesses, and other market actors. However, this dichotomy is now understood to be too simplistic: not only have the boundaries

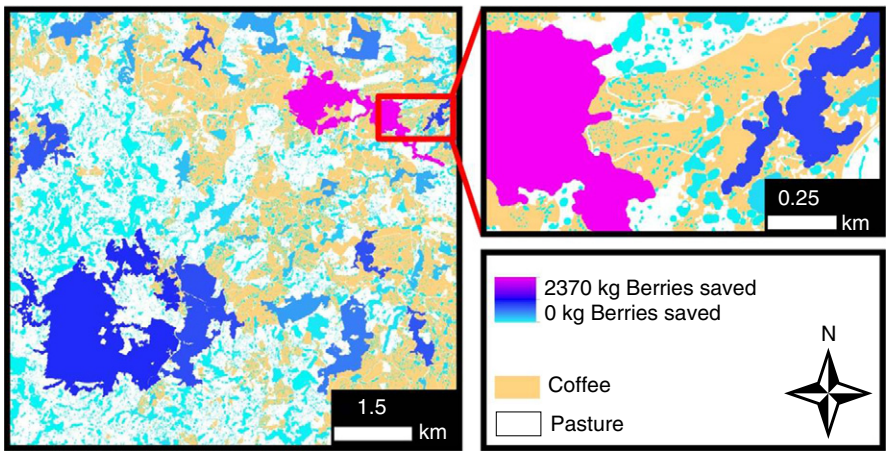

Figure 4 Pest control value of forest patches to coffee plantations in Southern Costa Rica forest provides habitat for the insectivorous birds that consume the coffee berry borer beetle (*Hypothenemus hampei*), coffee's most economically damaging insect pest. Maps show the estimated kilograms of coffee berries saved from infestation by each patch of forest across the Coto Brus Valley. Integrated together, the small, unprotected forest patches embedded within or adjacent to coffee plantations provided the majority of pest control value to coffee farmers.

between regulatory and market-based approaches blurred in many cases, but the range of market-based approaches has also proliferated to the point where further categorization is necessary (Lemos and Agrawal, 2006). This situation reflects a broader shift from the primacy of state institutions in environmental governance to the inclusion – and sometimes dominance – of other groups, including corporations, consumers, civil society organizations, and multinational organizations (Liverman, 2004).

Before describing the range of policy and programmatic strategies used to conserve and manage ecosystem services from agricultural landscapes, it is worth noting some challenges endemic to the governance of agricultural systems, which have limited the effectiveness of most if not all these strategies to varying degrees. First, in contrast to other ecosystem types that are major providers of ecosystem services (e.g., forests, wetlands, and water bodies), agricultural lands are predominately owned or managed by private individuals and companies, or in some instances collectively by rural communities. This means that government authorities generally cannot influence the use of these lands simply by adjusting management plans and policies for lands and water over which they have substantial control, as they might for a state-owned protected area or water body. Second, the historically private nature of agricultural enterprises means that there is little tradition of public sector regulation of agricultural activities, at least with regard to major agronomic decisions affecting ecosystem services, such as rural land use, tillage, planting, and soil fertility management.

Third, agricultural management systems are highly context-dependent (based on climate, soils, hydrology, and other factors), making it inappropriate to devise 'one size fits all' regulations and frequently inefficient to incentivize specific management practices, which may not be appropriate in all contexts. Fourth, most of the major ecosystem services and disservices from agriculture are 'nonpoint' in nature, meaning that they flow from the land itself, in heterogeneous patterns, and are, therefore, difficult to quantify, monitor, or regulate (Ribaudo *et al.*, 2010). In contrast, point source impacts, such as water withdrawals and factory emissions from a smokestack or effluent pipe, are much easier to monitor and regulate and have been the subject of many effective environmental regulations. Fifth, monitoring and enforcement in agricultural settings is always a challenge, given the dispersed, private nature of agricultural activities and the nonpoint nature of key ecosystem service outcomes. This is particularly so on the world's approximately 350 million small farms, where the transaction and administrative costs of policies and programs can become proportionately quite high.

Table 3 provides a basic typology of policies, programs, and instruments that may be used to conserve and enhance ecosystem services from agricultural landscapes. Each of these is described further below.

Government Regulation

Agriculture in most countries is a relatively lightly regulated enterprise when compared with other land uses, such as industrial facilities, mines, urban development, and even forestry. Land-use regulations restrict or prohibit agriculture in certain locales (e.g., protected areas, watershed conservation areas, and multiuse management zones) and in some instances aim to reduce the degree to which agriculture conflicts with the provision of important ecosystem services. On a broader scale, both Brazil and Indonesia have enacted temporary moratoria on deforestation for agricultural expansion, which have been credited with reducing the loss of ecosystem services associated with soybean and oil palm expansion, respectively (Macedo *et al.*, 2012). A limited number of regulation require on-farm protection of remaining natural ecosystems (e.g., remnant forest patches), or riparian buffers, recognizing their capacity to provide ecosystem services both within and beyond cultivated areas. Nonetheless, these regulations are quite limited overall, and, in many places where they exist, have been poorly enforced and widely ignored. A notable example is Brazil's Forest Code, which on paper requires farmers to establish mosaics of natural habitat within agricultural landscapes but in practice has been generally flaunted.

Regulation of certain farm inputs – particularly pesticides – is robust in many countries and may help to mitigate certain negative impacts of agriculture, including the negative off-site impacts on water quality. However, even where the most toxic pesticides are effectively regulated, use of other legal, but still toxic, pesticides may contribute to large aggregate impacts that diminish both water quality and habitat provision (Schiesari *et al.*, 2013). In particular, pesticide contamination can negatively affect the ecological communities in waterways, resulting in degradation or loss of the important services these communities provide (e.g., pest control services provided by mosquito fish in small channels near populated areas; fishing and other cultural services supported by rivers and streams).

Agriculture (and the ecosystem services it provides) may also be governed by broader regulations that apply across many sectors. However, these laws are not always applied fully in the context of farms and ranches. For instance, in the United States, agricultural operations enjoy a variety of statutory or de facto exemptions from otherwise strong environmental laws including the federal Clean Water Act, federal Endangered Species Act, and certain state endangered species acts. These exemptions highlight both the privileged political status that the agriculture sector enjoys in many countries and the difficulty in enforcing these types of laws in an agricultural context. They also underscore the need for interventions focused on ecosystem services that support rather than compromise production functions.

Market-Based Instruments

In the context of policy options, the term 'market-based' is used broadly to refer to strategies that seek to influence behavior by adjusting the price signals to various market actors, including farmers, corporations, and consumers. Such instruments are often intended to remedy 'market failures' that can occur when the providers of ecosystem services do not reap the full benefit of delivering these services, or when they avoid bearing the full cost when they diminish these services. For instance, farmers usually receive little or no monetary benefit from protecting wildlife habitat, although this is an important

Table 3 Typology of policies, programs, and instruments that may be used to conserve and enhance ecosystem services from agricultural landscapes

Type of policy, program, or instrument	*Level of state involvement*	*Role of farmers*	*Examples*
Government regulation ('command and control')			
Land use regulations	High (set and enforce regulations)	Subject of regulations	Land-use zoning; temporary moratoria; riparian buffer zone requirements
Regulation of agricultural inputs			Bans and restrictions on use of certain pesticides; prohibition on planting genetically modified organisms
Regulation of other agricultural practices			Good agricultural practices regulations focused on food safety
Other regulations affecting agricultural lands			Regulations on water, wetlands, and endangered species
Market-based instruments (*influencing price signals or incentive structures*)			
Taxes and subsidies	High (establish tax and subsidy policies)	Payer of taxes or recipient of subsidies	Earning tax credits for best management practices (e.g., Resource Enhancement and Protection Program in PA, USA) subsidies for no-till planters
Markets formed through regulation (e.g., cap-and-trade), leading to PES	Moderate to high (set regulations and oversee market)	Buyers or sellers of ecosystem services, where required or eligible to participate	Water quality trading, regulated carbon markets
Public sector PES	High (deploy funds and administer PES program)	Sellers of ecosystem services	Agri-environment payments (Europe), Farm Bill environmental programs (USA)
Private and voluntary PES	None or low	Buyers or sellers of ecosystem services	Various watershed, biodiversity, and carbon PES involving farmers
Eco-standards and certification	None to moderate	Sellers of agricultural goods produced in accordance with eco-standards	IFC Performance Standards, Rainforest Alliance, and Roundtable on Sustainable Palm Oil
Rural development and farmer assistance programs			
Technical assistance and cost-share programs	None to high (some programs are funded or run by the public sector, others by private or civil society entities)	Program participants and beneficiaries	Farm Bill programs for conservation measures on US farms
Education and training programs			Conservation Farming Unit (Zambia)
Rural development projects and programs			Sustainable Land Management investments (Global Environmental Facility/World Bank)

Note: Some of these instruments also serve additional aims or are not always used to manage ecosystem services in agricultural landscapes. The abbreviation PES stands for payment for ecosystem services.

public benefit. Conversely, when fertilizer runoff from farms contributes to downstream eutrophication and its attendant environmental and economic harms, the farmers responsible for these harms usually bear no economic consequences. Market-based instruments can address such environmental 'externalities,' which would otherwise result in suboptimal delivery of or investment in the provision of ecosystem services.

The most long-standing types of market-based instruments are various forms of taxes and subsidies, which are deployed across many different economic sectors, including agriculture. Historically, agricultural subsidies (e.g., for fertilizer inputs) played a significant role in promoting both the expansion and intensification of agriculture to the significant detriment of ecosystem services. However, taxes and subsidies can also promote conservation-friendly agriculture that may deliver increased levels of ecosystem services. For instance, in Kazakhstan, the government in 2008 began subsidizing farmers to adopt conservation agriculture technologies – including continuous soil cover, direct seeding, and no-till management – that are credited with helping to increase farmer yields and profitability while reducing soil erosion.

PES are abroad set of market-based instruments that have proliferated since the mid-1990s to channel new investment in ecosystem services. Formally, PES has been defined as voluntary transactions between ecosystem service seller(s) (such as farmers or other land managers) and ecosystem service buyer (s) (such as water users or conservation organizations) that provide cash or other payment in exchange for the provision of specific defined ecosystem services (Engel *et al.*, 2008). In practice, however, many PES schemes do not conform to this definition, for instance, because they do not target specific

ecosystem services or make payments contingent on actual delivery of these services (Muradian *et al.*, 2010). For instance, many publicly administered PES schemes – including those in Costa Rica, Mexico, Europe, and the United States – function more like environmentally focused farmer subsidy programs than true conditional payments targeted to deliver the largest quantity of ecosystem services for the least cost.

Ecosystem service payments that involve the creation of open markets (as opposed to government payments) are likely to more closely resemble market-based instruments in the classic sense of the term. In the United States and other countries, such markets have been established through regulations that cap total levels of pollution or degradation to a given ecosystem or ecosystem type but enable landowners to trade the limited allocated rights to pollute or degrade. Such 'cap-and-trade' mechanisms are intended to reduce the overall cost of achieving specific environmental goals and have resulted in robust markets for wetland mitigation, wildlife habitat, and agricultural runoff, among other ecosystem services and disservices. Truly voluntary private markets for ecosystem services involving farmers as ecosystem service sellers have also developed in places, although on a smaller scale. These markets have formed around carbon sequestration, watershed conservation, and biodiversity protection, with buyers ranging from private companies (e.g., water bottling businesses), to individuals and corporations wishing to offset their carbon emissions, to conservation organizations.

On a global scale, PES makes only a modest contribution to incentivizing increased ecosystem service delivery from agricultural landscapes. However, this contribution is proportionately much larger in the United States, Europe, and China, where large government PES programs – totaling perhaps US$20 billion per year – exist to support watershed protection, biodiversity conservation, and esthetic protection ('landscape beauty') services (Milder *et al.*, 2010). The future size of ecosystem service markets affecting farmers remains uncertain: although it is clear that farmers deliver critical ecosystem services to a wide range of stakeholders, it is not clear whether these beneficiaries will actually be willing to pay for such services on a large scale, or whether markets will be formed that support the cost-effective procurement and management of these services. The future regulation of greenhouse gas emissions (or lack thereof) at national or global level is a critical factor, as farmers stand to participate heavily in carbon markets if they coalesce at full scale.

Experience from a wide range of contexts suggests that PES in agricultural landscapes is likely to be most effective and scalable where management practices that sustain or increase ecosystem service delivery also support agricultural productivity or profitability. In these situations, PES can provide farmers with supplemental revenue that helps them to overcome initial investment barriers or other constraints to adopting more conservation-friendly management practices (FAO, 2007; Majanen *et al.*, 2011). However, where there is a high opportunity cost to manage agricultural landscapes for increased levels of ecosystem services, PES schemes are unlikely to be able to compete with the profitability of environmentally destructive farming and will find few willing sellers of ecosystem services. A prime example is at the agricultural frontiers of major commodity crops, such as palm oil (Southeast Asia), where levels of carbon payments supported by ecosystem service markets may provide insufficient incentive to prevent deforestation and the significant loss of ecosystem services (Fisher *et al.*, 2011).

A final market-based instrument is the adoption and use of voluntary sustainability standards – often called 'eco-standards' – and associated 'eco-certification' labels for agricultural products and investments. Agricultural sustainability standards are sets of social and environmental criteria put forth to define and encourage sustainable farming by providing market recognition for sustainable producers. These include standards developed and managed by nonprofit organizations (e.g., Fairtade, Rainforest Alliance, and UTZ Certified), multi-stakeholder 'roundtables' for various commodities (e.g., for soybeans, palm oil, sugar, beef, and cotton), individual food companies (e.g., Unilever, Nestlé, Mars, and others), and the finance sector (e.g., IFC Performance Standards and the Equator Principles). By participating in such schemes, farmers, traders, and food companies that produce and sell certified products may benefit from improved market access or market share, price premiums, or improved legitimacy and reputation in the eyes of consumers and regulators. Most, if not all, agricultural sustainability standards include provisions intended to help conserve biodiversity, including sensitive habitat that supports organisms of conservation concern, and ecosystem services (e.g., water purification and water flow regulation and soil fertility and erosion control) (UNEP-WCMC, 2011). Thus, e co-certification may provide monetary incentives for farmers to maintain or enhance ecosystem services, although such incentives are not necessarily explicit or direct with respect to specific ecosystem services.

Rural Development and Farmer Assistance Programs

Governments, international donors, civil society organizations, and others have been involved for decades in supporting agricultural development around the world. In the past 10–15 years, an increasing proportion of these efforts have begun to orient program objectives and activities toward maintaining or increasing flows of ecosystem services in concert with increased yields and farmer profitability. Some initiatives, particularly in developed countries, provide technical assistance, farmer training, or cost sharing of on-farm investments to reduce the negative environmental impacts of agriculture. For instance, a variety of programs funded under the US Farm Bill provide technical assistance and cost sharing for practices such as improved water management structures, erosion control practices, integrated pest management, and transitioning to organic practices.

In the developing world, agricultural development efforts that strongly integrate ecosystem management have been advanced under a variety of names and approaches. A 2006 review surveyed 286 such interventions covering a total of 37 million hectares and found evidence of substantial increases in crop yields together with water-use efficiency gains and potential gains for carbon sequestration and other ecosystem services (Pretty *et al.*, 2006). More recently, the World Bank and other multilateral institutions have supported 'sustainable land management' programs in dryland regions of dozens of countries to enable farmers and pastoralists to increase

productivity while conserving water, forests, and other natural resources on which rural livelihoods depend (World Bank, 2008b). The recent dialog around 'climate-smart agriculture' prioritizes the conservation of ecosystem services that help to build resilience in agroecosystems (e.g., water flow regulation, flood control, water storage, and erosion protection) and allow farmers to maintain food production in changing or extreme weather conditions as well as access other livelihood resources if crops fail. In addition, climate-smart agriculture promotes climate change mitigation through carbon sequestration in farm soils and vegetation as well as reduction of greenhouse gas emissions from sources such as livestock, rice paddies, and soil denitrification.

Knowledge Gaps

Although scientific understanding of ecosystem services and their biological mediators in agricultural landscapes has grown dramatically in the past couple of decades, several critical knowledge gaps remain.

First, there is a need to develop mechanistic understanding of the organisms, guilds, and ecological communities that provide ecosystem services (Kremen and Ostfeld, 2005; Kremen, 2005). Identifying key ecosystem service providers and understanding their requirements for performing the biological functions that underpin service delivery are essential for effective management of agroecosystems that deliver both sustained crop yield and ecosystem services. However, to date, these biological requirements are known for only a small subset of key ecosystem service providers (e.g., area requirements for pollination by native bees; Kremen *et al.*, 2004). Second, there are relatively few studies that examine quantitative measures of yield and ecosystem services in the same system (Milder *et al.*, 2012). For instance, although recent metareviews have included 300 or more comparisons of yield effects relative to conventional systems (e.g., Seufert *et al.*, 2012), relatively few studies provide rigorous data on paired outcomes for yield as well as ecosystem services. A third knowledge gap is the lack of studies that link management practices to ecosystem service outcomes at multiple scales. Measuring the spatial and temporal scales over which ecosystem service providers deliver key services is imperative to addressing this gap (Kremen and Ostfeld, 2005). Specifically, building understanding of how ecosystem functions are influenced by the species and communities within an area is needed to understand how their attributes and services can aggregate at different scales from cultivated fields to broader regions, including cultivated and noncultivated areas.

Addressing these knowledge gaps is essential to designing and managing multifunctional agroecosystems. Continued work on this front is needed to answer the growing call for agricultural landscapes that can simultaneously meet production and conservation goals.

Glossary

Biochory Passive, unintentional transport of spores, eggs, microbial cells, or small animals by organisms that move in the litter and soil, thereby promoting the dispersal of almost immobile organisms.

Bioturbation Soil mixing carried out by organisms in soils, mainly earthworms, termites, and ants, plus a few Coleoptera, nymphal Cicadidae, Isopoda, or Grylotalpidae ('mole crickets'). Bioturbation may be effected by ingesting the soil and passing it through the animal gut (earthworms and humivorous termites), or by constructing mounds, digging galleries and chambers to accommodate colonies and food reserves (ants and foraging and fungus-growing termites). Roots also affect some degree of bioturbation through creating holes that are further used by other organisms as habitats and passageways for movement once the root has died and disappeared.

Catena of soils A succession of soils arrayed down a slope, with profiles changing according to their topographic position. The low-lying parts of the catena generally have a higher moisture status and receive elements eluviated, detached, and transported from the higher parts. The upper parts of the catena may become depleted in clay and nutrients by these processes.

Chemolithotrophy The ability to use energy obtained by the oxidation of inorganic compounds.

Comminution The physical transformation of leaf and root litter with limited chemical (digestive) decomposition. This is an essential process in litter recycling whereby large plant-derived structures, such as leaves, are progressively fragmented into increasingly smaller pieces, thereby increasing the surface area exposed to microbial attack.

Drilosphere A word coined by Bouché (1972) that describes the 'functional domain' created within soil by earthworms ('drilos' in Greek) and is analogous to the well-recognized 'rhizosphere,' the sphere of influence of roots. The drilosphere is thus the sum of earthworms and the structures that they create in soil as casts, galleries, and pores of different sizes and shapes, together with the communities of smaller organisms, invertebrates, and microorganisms that inhabit the habitats thus constructed. The earthworm gut is the critical component of the drilosphere in which earthworm digestion in conjunction with microorganism activity provides the energy necessary to maintain this structure.

Geophagous An organism that ingests soil. Endogeic earthworms and humivorous termites are the main groups using this feeding regime. They actually digest the organic part of the soil, in a mutualistic association with the ingested microflora. The activity of the microflora is greatly enhanced during gut transit and makes part (usually some 10%) of the ingested organic matter available to the earthworm as a product of microbial digestions. A further fraction, as yet unevaluated, is converted into microbial biomass.

Inoculation (with microorganisms, invertebrates, or plants) Addition to the soil of an organism that is absent or present in such low quantities that its effect on, for example, soil structural formation or plant protection is no longer observed. Inoculations are possible only if suitable conditions are present. Re-inoculating an organism that has disappeared from the environment due to impairment of its natural living conditions requires restoration of these conditions. Inoculation of exotic species of microorganisms or invertebrates is often rendered impossible through competition or other effects of local species, an important point to consider when trying to improve plant growth by using microbial supplements and inoculates.

Mineralization/immobilization When microorganisms use a substrate to meet their maintenance and growth needs, they secrete enzymes that degrade the substrate and absorb the metabolites thus made assimilable. Nutrients are absorbed according to the needs of the organism in proportions that can be fixed or variable. When nutrients are assimilated in excess, they are secreted into the external medium in mineral forms as, for example, NH_4 or NO'_3 for nitrogen. When the element is deficient in the substrate used, microorganisms use whatever source of the element that occurs in the soil in mineral form. The result is a decrease in concentration of this mineral element and is referred to as immobilization within the microbial biomass.

Protocooperation An association between microbial and other communities that allows the degradation of a substrate which they would not be capable of degrading alone.

Stoichiometric imbalances Occur when the composition of assimilable nutrients in a food source is so different from their relative tissue concentrations that growth of organisms using this resource becomes dependent on the concentration of the most limiting nutrient.

Theca The external skeleton of some Protoctists of the thecamaebian group and formed from silica. This often sub-spherical envelope protects the organism from predators and drought.

Introduction

The Green Revolution boosted agricultural production approximately 2.5 times and was associated with an approximately 40% price reduction in the cost of food (MA, 2005). Following on the euphoria of this success there has been increasing pressure to diversify production and to improve the planet's environment (Hubert *et al.*, 2010). Successful realization of this pressure will require better soil management. However, current conditions are very different from what they were 50 years ago. The success of the Green Revolution came at the expense of the natural capital, such that 18 of the 24 currently acknowledged ecosystem services have been impaired. Although soils have aided climate regulation by sequestering an estimated 2 Gt carbon (C) per annum from fossil fuel burning, they have lost part of their capacity to regulate hydrological fluxes and nutrient cycles and therefore to support plant production.

The soils of the earth are now being asked to produce 70% more food over the next 35 years, while also producing biofuels, regulating climate through further C sequestration, and helping to conserve biodiversity. However, the other side of this coin is the declining amount of land remaining available for conversion to agroecosystems and the increased cost of energy, which has led to a substantial increase in the price of fertilizers. Further, world sources of phosphorus (P) are being rapidly depleted and the toxic effects of pesticides are now forcing the replacement of these former pillars of intensive agriculture with new technical options.

Agriculture now needs to sustain high levels of production while preserving or restoring the natural capital of the soil. Maintenance of an appropriate level of soil biodiversity is critical to achieving this goal, but in order to protect the soil resource and optimize its long-term use, new land use practices are needed to be developed, based on much greater understanding of the factors controlling its functioning.

This article summarizes the current knowledge of the composition and taxonomic richness of the soil biota. It then examines the participation of the soil biota in the major soil functions and discusses ways to reconcile the conservation and/or improvement of this natural capital with the production of critical ecosystem goods and services.

Components of Soil Biodiversity

Soils were the first terrestrial biotope to be colonized from the marine environment. Hence, they have retained a large component of aquatic organisms in their water-filled pore spaces while evolution has progressively added aerial organisms adapted to living within the soil air spaces. Several hundred millions of years of continuous evolution in this confined environment has conserved some of the most primitive forms of life. It has also created novel associations among organisms with no equivalents in less-constraining parts of the ecosystem.

General Constraints to Life in the Soil Habitat

Life in soil is constrained by three major soil features (Lavelle and Spain, 2001; Lavelle, 2012):

1. A compact soil matrix that possesses few open pores as habitat and limited systems of connected pores, thereby constraining internal flows of air and water;
2. Low-quality food, composed of dead leaves and roots rich in decomposition-resistant polyphenolic compounds, humified and stabilized organic matter, living roots, and other organisms; and
3. Variable moisture conditions that result in the alternation of flooding and drought at the scale of a soil pore, with increasing incidence of saturated anaerobic conditions as pore size decreases.

No single group of soil organisms has been able to adapt optimally to living with all these constraints. Although the smallest microorganisms find relatively constant conditions in the water-filled pores, they have a very limited ability to remain active in aerial conditions. Consequently, once they have exhausted their existing substrate they enter a resting stage – most commonly as a spore or a small dormant bacterial colony. Thus, soil-based microorganisms frequently exist in dormant stages; however, fungi are more active and may be more readily transported by biotic or abiotic agents than bacteria (Lavelle and Spain, 2001). Fungal hyphae, able to cross between pores without water, are generally better adapted to higher water potentials than bacteria, which makes them more tolerant of water deficit. They often rely on invertebrates for the dispersion of their spores (Lavelle and Spain, 2001).

Dormant microorganisms can resume activity when such physical or biological agents as water flows and disturbance caused by mixing, bioturbation, or biochory by roots and invertebrates move microorganisms toward a new source of food. For example, spores of mycorrhizal fungi may be activated when they come into contact with root exudates, leading to the initiation of a mutualistic symbiosis with the host plant. Through this association, a continuous supply of plant-derived carbon substrates is supplied to the fungus, which provides the energy for it to actively colonize the soil and so provide its host plant with soil-derived nutrients (Smith and Read, 2008).

In contrast to microorganisms, large soil invertebrates of the 'soil ecosystem engineer' group, which are principally termites, earthworms, ants, and some Coleoptera and Isopoda, have developed the ability to move and work the soil (bioturbation). This is achieved either by digging with strong legs or mandibles or, as in the case of earthworms, by ingesting the soil and compacting it with their hydrostatic skeleton. These invertebrates, however, have very limited abilities to digest litter and soil resources on their own and consequently interact with microorganisms to take advantage of their outstanding capacities for digestion.

Adaptive Strategies of Soil Fauna

The primary indicator of general adaptive strategy is size (**Figure 1**: Decaëns, 2010 after Swift *et al.*, 1979).

The smallest animals – micro-fauna – are invertebrates smaller than 0.2 mm. They are the predators of the microorganisms and principally comprise proctoctists, nematodes, and a number of groups of lesser importance, such as tardigrades and rotifers. Most of the micro-fauna consume fungi or bacteria and are, therefore, referred to as 'microbial grazers.'

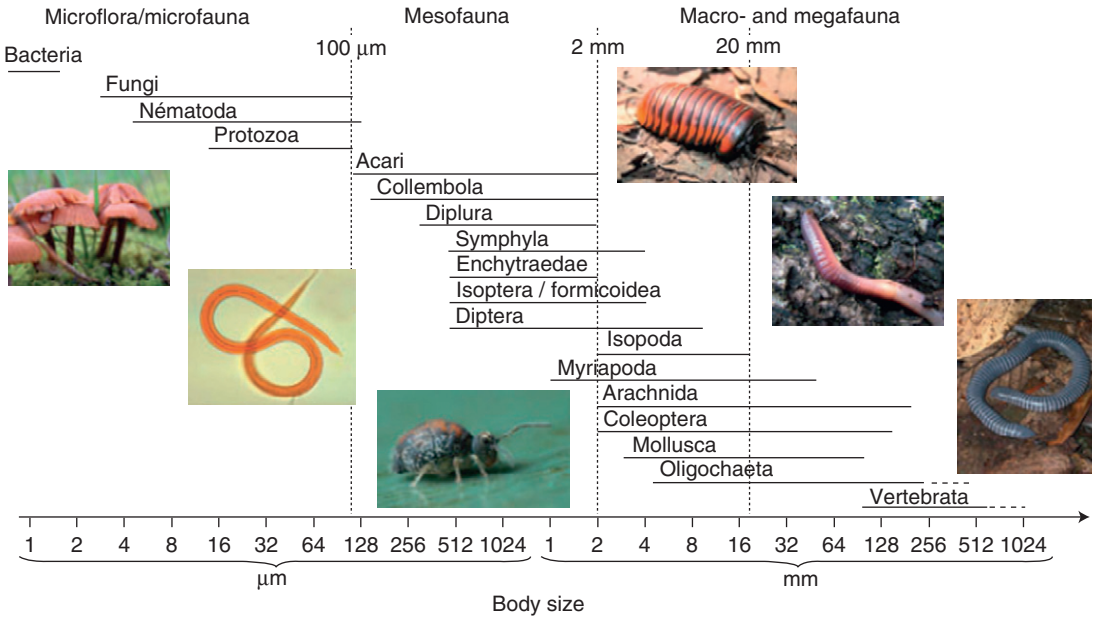

Figure 1 Representation of the main taxonomic groups of soil organisms on a body size basis. Reproduced from Decaëns, T., 2010. Macroecological patterns in soil communities. Global Ecology and Biogeography 19, 287–302 after Swift, M.J., Heal, O.W., Anderson, J.M., 1979. Decomposition in Terrestrial Ecosystems. Oxford: Blackwell Scientific.

They exert the primary control of microbial populations and communities. As a result of stoichiometric imbalances, they excrete available forms of mineral nitrogen (N) and other nutrients into the soil solution. Consequently, the complex foodwebs that they form are of great importance to the biological control of microbes and to soil organic matter (SOM) dynamics and the cycling of nutrients (Moore *et al.*, 2004). This is especially true in ecosystems where arid conditions, deep disturbance, or agrichemical stress restrains the activities of larger invertebrates. Such foodwebs based on microbial grazing are of lesser relative importance in natural ecosystems where ecosystem engineers have large populations (Wardle and Lavelle, 1997; Lavelle *et al.*, 2006).

The next group, the meso-fauna, and some large litter-dwelling invertebrates feed on above- and below-ground dead plant material. The comminution and limited digestive processes that they carry out allow some degree of composting. They have been called 'litter transformers' and they accelerate nutrient release on short time scales. Commonly, their fecal pellets are subjected to microbial incubation, thereby releasing assimilable compounds, which will then be consumed by themselves or other invertebrates. This is known as 'external rumen digestion' (Swift *et al.*, 1979; Hassall and Rushton, 1985). Alternatively, the released nutrients may be utilized by microorganisms, thus increasing the microbial biomass.

The largest invertebrates are the 'soil ecosystem engineers.' Members of this group have developed the most efficient interaction with microorganisms and have a sophisticated mutualistic digestion system contained within their own gut (Lavelle *et al.*, 1995). Efficient digestion allows the capture of the large amounts of energy required to ingest several times their own weight of soil daily or to dig dense gallery networks (Lavelle *et al.*, 1997). Where ecosystem engineers are active, the entire upper 10–15 cm of soil may be ingested over the course of a couple of years. This creates a macro-aggregated structure that has highly favorable physical properties, providing resistance to erosion and the promotion of water infiltration and storage. Many ants are, however, predators and are clearly an exception to the above. The 'leaf cutter ants' in particular, and some termites, enter into 'external rumen' relationships with microorganisms; some termites also produce an efficient suite of enzymes in their mid guts.

The correspondence between invertebrate size and function tends to spread their activities across a number of well-separated and discrete scales. The proximate control of microbial communities and their activities by micro-foodwebs occurs mainly within pores and aggregates 50–100 µm in size (Hattori and Hattori, 1976). Litter transformers, however, vary in size from mm to cm and operate at larger scales in the leaf or root litter. The ecosystem engineers operate at even larger scales (from cm to >m), creating structures such as ant or termite colonies, or patches where earthworm populations dominate (Ettema and Wardle, 2002; Rossi, 2003; **Table 1**).

Different Groups and Their Respective Species Richnesses at Local and Global Scales

Although soil biodiversity comprises a large part of global diversity, no precise data are available (**Figure 2**). Recent estimates of total diversity suggest that both bacteria and fungi may each comprise as many as 1.5 million species.

Generally, many of the larger organisms represented in the soil biodiversity have been described, but estimates suggest that only 0.1% of species in the micro-fauna and micro-organisms have been described so far (Decaëns, 2010; Wurst *et al.*, 2012).

Another interesting feature of soil organisms is the relative rate of endemism – measured by the local α, to regional β, or

Table 1 Main parameters of the adaptive strategies of organisms in soils

Functional group	*Microorganisms*	*Micro-fauna*	*Meso-fauna*	*Macrofauna*
Body width	0.3–20 mm	$<$0.2 mm	0.2–10 mm	$>$10 mm
Taxa	Bacteria and fungi	Proctoctists nematodes	Microarthropods Enchytraeidae	Termites earthworms myriapoda, ants, etc.
Water relationships	Hydrobiont	Hydrobiont	Hygrobiont	Hygrobiont
Interactions with microorganisms	Antibiosis mutualism competition	Predation	Predation	Mutualism (external rumen and facultative/obligate internal mutualism)
Ability to change the physical environment	Very limited	None	Limited (fecal pellets)	High (galleries, burrows, and macro-aggregates)
Resistance to environmental stresses	High (cysts, spores, etc.)	High (cysts, spores, etc.)	Intermediate	Low but possible behavioral compensation
Intrinsic digestive capabilities	High	Intermediate	Low	Low

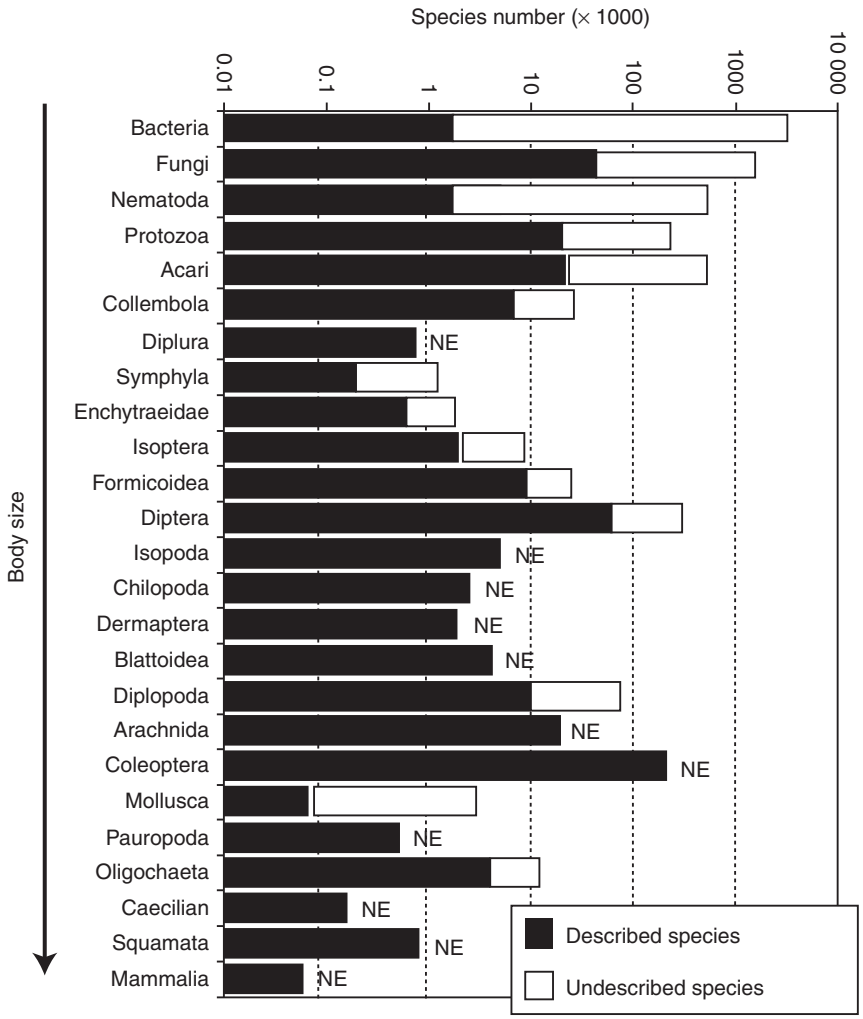

Figure 2 Biodiversity range in dominant soil-dwelling organisms. NE, not estimated. Reproduced from Decaëns, T., 2010. Macroecological patterns in soil communities. Global Ecology and Biogeography 19, 287–302.

global γ diversity. Generally the smallest microorganisms/microflora have the largest worldwide distributions. The arbuscular mycorrhizal fungi, for example, are relatively ubiquitous, and a significant proportion of the known species may be found at a single site (e.g., 33% in Amazonia) (Stürmer and Siqueira, 2011). Earthworms, however, have very high rates of endemism and two points separated by 500–1000 km have little chance of sharing common species; nonetheless, a small set of populous species may be found almost everywhere (Lavelle and Lapied, 2003).

Organization of Soil Biodiversity

Species of the same taxonomical group (families or orders) can adapt to soil conditions in different ways and so belong to different functional groups; the number and relative importance of which represent their functional diversity. To avoid competition, communities typically adapt during the course of evolution with limited niche overlap among species.

However, adaptation to soil conditions has led organisms to develop interactions with other organisms of different taxonomic groups at the same site. For example, earthworms depend on interactions with microflora for their digestion, whereas microorganisms are dependent on bioturbation and the habitats created by earthworms to resume activity after periods of dormancy in microsites where organic substrates were exhausted or out of reach. Similarly, small invertebrates, microorganisms, and the roots of plants occupy these nutrient-rich habitats created by earthworms and other ecosystem engineers. Roots usually follow earthworm galleries and fine roots tend to concentrate in fresh casts, which sometimes have high concentrations of easily absorbed nutrients and even growth hormones

As a result, the presence and abundance of populations of a given species may be as dependent on its relationships with species of the same functional group within a community of species of the same family or order ('horizontal biodiversity'), as with soil organisms of other functional groups (the 'vertical biodiversity').

Within-group diversity: Functional groups

Communities of a given functional group of soil-dwelling organisms are comprised of populations with well-developed functional differences. In each group, functional classifications have been produced to describe niche partitioning among different species and the diversity of functions that they fulfill (Table 2).

Microorganisms, such as fungi, bacteria, and archaea, are responsible for more than 90% of the chemical transformations associated with organic matter decomposition and nutrient cycling. They can be classified according to the range of their abilities to digest and degrade specific chemical substrates ranging from easily assimilated glucids and proteins to complex humic and phenolic molecules that require very specific metabolic abilities. Simple molecules, like glucose, may be metabolized by most microorganisms, whereas the most complex ones, including cellulose and starch, are used by fewer species, usually fungi and actinobacteria. Finally, the phenol–protein complexes that comprise 85% of dead leaf and root nitrogen may only be decomposed by a few basidiomycetes of the 'white-rot' fungal group (Lavelle and Spain, 2001; Kadimaliev *et al.*, 2010). Methanotrophs and methylobacteria use substrates with only one molecule of carbon, whereas cellulolytic bacteria are able to decompose cellulose polymers that have thousands of carbon molecules. Only a few soil arthropods and earthworms have efficient cellulolytic enzymes and are able to digest cellulose because of symbiotic interactions with microorganisms in their guts. Complex substrates are usually degraded by consortiums of diverse microorganisms (Zanaroli *et al.*, 2010) in protocooperative interactions. The nutrient composition of organic matter, specifically expressed by the C:N, C:P, and C:S ratios, also plays an important role in the processes of mineralization or immobilization in organic molecules of nutrients within the soil. Mineralization requires high relative concentrations of nutrients (e.g., C:N ratio < 20) and is inhibited when nutrient deficiencies limit the growth and activities of the decomposers.

Another functional classification of microorganisms is based on their mode of respiration: aerobic, anaerobic, or microaerophilic. This reflects their capacities to be active in different oxygen environments.

Finally, the decomposition of organic matter is associated with numerous biochemical reactions linked to the nutrient cycles mediated by microorganisms, principally bacteria. For example, chemolithotrophy is the ability to use the energy obtained by the oxidation of inorganic compounds; thus chemolithotrophs mediate reactions that are important steps in nutrient cycles, such as nitrification, denitrification, methanogenesis, and the use of reduced sulfur, copper, iron, and other

Table 2 Major functional groups in some groups of soil-dwelling organisms

Taxa	*Functional groups*					*References*
Bacteria	Bacteria	Carbon cycle: e.g., photosynthetic, methanogenic, methylotrophs, and celulolitic	N cycle: e.g., N2 fixers, nitrifiers, amonifiers, and denitrifiers	P, K, Ca, and Mg: Solubilizers	S: Oxidation of sulfur, thiosulphate, tetrathionate or sulphides Reduction of sulfate ions to hydrogen sulfide	Moreira and Cassia (2013)

Ants	Omnivorous	Predators	Fungus growers	Homoptera breeders		Korasaki *et al.* (2013)

minerals. As an example, biological nitrogen fixation and the reduction of N_2 to NH_3 is mediated by some specialist bacteria.

Invertebrate functional classifications reflect their responses to the three main constraints they face in the soil.

Micro-fauna (protoctists, nematodes, and a few other groups generally of a size $<200\ \mu m$) are mainly predators of microbes and other smaller invertebrates or herbivores. They are aquatic organisms that have no ability to create habitats in soil by digging, or bioturbation. They survive dry periods with a large variety of extraordinarily efficient mechanisms involving dormancy in different forms (spores, cysts, and desiccated individuals) (Lavelle and Spain, 2001).

Protoctists comprise three main taxonomic groups: ciliates, amoebae, and flagellates. Each group is characterized by different capacities to resist drought: amoebae, for example, can be more active than other proctoctists, because they can enter very small pores and shelter in theca that they secrete.

Nematodes are classified according to their feeding regimes (trophic groups): plant parasites, bacterivores (bacterial feeders), fungivores (fungal feeders), predators, and omnivores (Bongers, 1990). The relative proportion of 'persisters,' with relatively slow population turnover (k strategists), to 'colonizers,' with highly active turnover (r strategists), has been used to calculate the 'maturity index' of soils. It is considered a reliable indicator of the state of a soil and includes all soil nematodes except the plant parasites. A high maturity value indicates a low level of soil general stress due to drought, or nutrient deficiency, whereas a low value denotes high soil disturbance and difficult conditions for life, such as those generally found in soils subject to intensive agriculture (Bongers, 1990).

Ecosystem Engineers

Earthworms have been classified into three groups (epigeics, endogeics, and anecics) according to their main feeding habits and habitats. A suite of biological traits (morphology, anatomy, feeding regime, and demographic profile) is associated with these basic adaptive strategies. Epigeics are very active, small, and thoroughly pigmented earthworms that feed on fresh leaf litter and live within the surface litter itself. Their small size and use of a relatively rich food allow fast growth and active reproduction, a necessary demographic strategy in the face of high mortality from predators and the unstable moisture conditions that occur within their habitat. In contrast, Endogeics live in the soil and feed on it, having a purely geophagous regime based on the consumption of soils of high (polyhumic), medium (mesohumics), or low (oligohumics) organic matter contents (Lavelle, 1983). Anecics are very large earthworms ($>$ 20 cm in length) with an anterodorsal pigmentation. They live in vertical galleries that open at the soil surface and feed on a mixture of partly decomposed leaves and soil. The conditions of the humid tropics favor communities of large dominant mesohumic and oligohumic endogeic populations, whereas with the declining temperature the proportion of epigeics and polyhumics increases. The decrease in the efficiency at lower temperatures of the mutualistic digestion based on interactions with ingested soil bacteria (Barois and Lavelle, 1986; Lavelle, 1983) forces earthworms to rely on higher quality resources, thus favoring litter feeders rather than geophagous organisms.

In cropped agroecosystems, earthworm populations often decline as survival, growth, and reproduction are severely affected by the general decrease in organic resources or the unfavorable temperature and moisture conditions during the frequent periods when tilled soil is bare or treated with pesticides. Thus, in intensive European cropping systems, endogeics may become dominant, as long as the intensification does not exceed a still to be identified degree. Permanent pastures are often the habitat of large communities of anecics (Lavelle and Spain, 2001).

Ants have been classified according to several criteria: feeding regime (herbivores feeding on grains or cultivated fungi, aphid growers, and carnivores (Korasaki *et al.*, 2013); behavior (dominant or submissive); habitat (soil 'cryptic' or tree dwelling); or whether they are specialists or generalists (Andersen, 1995). For practical field work, ants can be classified into six main categories: subterranean carnivores (specialists or generalists); litter-based carnivores (specialists or generalists); arboreal/epigeic carnivores (specialists or generalists); subterranean herbivores; litter-based herbivores; or arboreal/epigeic herbivores (Bignell *et al.*, 2008).

Termites have been classified according to their feeding behaviors with additional subdivisions based on the nature and location of the nest.

Self-organization between groups across five-size scales

Self-organization that creates interactions among organisms of different types, with complementary functions, results in the concentration of biological activities at different scales, nested into one another (Lavelle *et al.*, 2006). Five relevant scales of physical structure have thus been identified with regard to soil physical organization (**Figure 3**). At each scale, interactions among organisms of one or more groups develop within the boundaries of structures, such as biofilms, meso-aggregates, or the accumulations of biogenic structures of invertebrate ecosystem engineers (Lavelle *et al.*, 2006). Structures at Scale 1 are generally embedded into larger scale structures made or inhabited by larger organisms that organize space on larger scales. For example, the rhizosphere, at Scale 3, hosts structures of Scale 1 (the bacterial colonies that develop at the surface of the root) and Scale 2 with communities of micropredators and the microenvironment in which they live.

Although these scales are implicitly acknowledged, based on empirical observations, such a discrete organization of the soil environment is still not proven. Although discrete patterns of physical organization have been observed in both porosity and aggregate size distribution across a limited range of scales (Menendez *et al.*, 2005; Globus, 2006; Fedotov *et al.*, 2007), data are still rather scarce and fragmentary.

Scale 1: Microbial biofilms and colonies. The smallest habitat in soils is represented by assemblages of mineral and organic particles approximately 20 μm in size, called micro-aggregates (**Figure 3**, Scale 1). Microorganisms in these microsites are involved in most chemical transformations that result in organic matter cycling and improved soil nutrient fertility. Guts of invertebrate ecosystem engineers or fecal

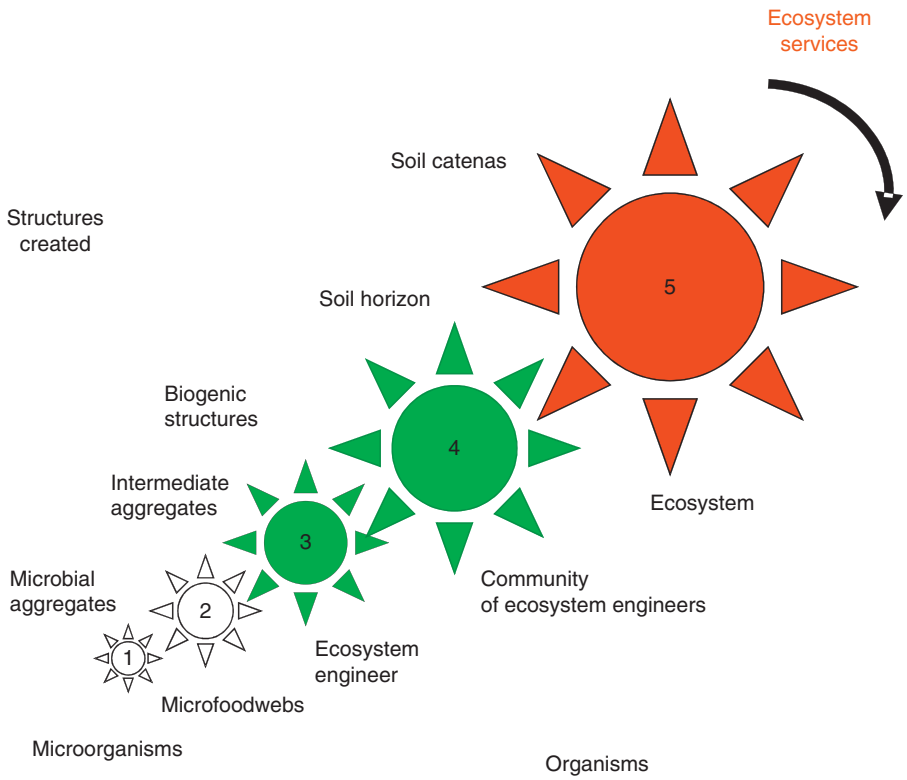

Figure 3 Self-organizing systems in soils at different scales from microbial biofilms and aggregates (1) to intermediate aggregates, (2) individual ecosystem engineer functional domains, (3) mosaics of functional domains in an ecosystem, (4) landscape, (5) and the biosphere (6, not represented), where ecosystem services are delivered along soil catenas. A community of interacting organisms, a set of physical structures that they inhabit and, in some cases, have created themselves, and the processes that operate at this scale of time and space define each scale. Modified from Lavelle, P., Decaens, T., Aubert, M., *et al.*, 2006. Soil invertebrates and ecosystem services. European Journal of Soil Biology 42, S3–S15.

pellets of litter transformers (Scale 3) are typical microsites where these Scale 1 structures are to be found.

Scale 2: Micropredator foodwebs in meso-aggregates. At a scale of approximately 100–500 μm, micro-aggregates form assemblages that leave spaces among them where micropredators, such as nematodes and protoctists, can feed on microbial biomass, thus controlling their populations and activities. Specific assemblages of microorganisms in the rhizosphere, such as mycorrhizal fungi, also operate within pores of this size scale representing an autotrophic option for meso-aggregate interactions (Högberg and Read, 2006; Grayston *et al.*, 1998).

Scale 3: At the scale of decimeters to decameters, ecosystem engineers and abiotic factors determine the architecture of soils through the accumulation of aggregates and pores of different sizes: micro-aggregates of Scale 1; meso-aggregates of Scale 2; and the macro-aggregates that they produce (Lavelle, 2002). These spheres of influence (or functional domains) extend horizontally over areas ranging from decimeters (e.g., the rhizosphere of a grass tussock) to 20–30 m (drilosphere of a given earthworm population) or more and from a few centimetres up to a few meters in depth, depending on the organism (Decaëns and Rossi, 2001; Jimenez *et al.*, 2006).

Scale 4: Functional domains are distributed in patches that may have discrete or nested distributions and form a mosaic of patches (Scale 4). Such a mosaic has been described, for example, by Rossi (2003), who observed the distribution of two groups of earthworms with opposing effects on soil aggregation. One group, called 'compacting' earthworms, stimulates soil macro-aggregation through the accumulation of large ($\sim$1 cm) compact casts, which reduce soil macroporosity (Blanchart *et al.*, 1997). 'Decompacting' earthworms, however, have the opposite effect by breaking large aggregates into smaller pieces. This reduces the bulk density of the soil and allows an increased density of rootlets in this more favorable environment. More complex spatial domains of ecosystem engineer communities probably mix the structures of termites, ants, earthworms, and plant roots, although their structure and the relationships between their different constituents have very seldom been described or understood (**Figure 4**).

Scale 5: Ecosystem and landscape. At the landscape level, different ecosystems coexist in mosaics with often clearly visible patterns. The occurrence and distribution of land cover types in landscapes may result from natural variations in the environment or human land management. Soil formation processes, for example, are very sensitive to topography, which is reflected in the formation of catenas of related soils from upper to lower lying areas. Significant differences in soil type at this scale often determine different vegetation types and hence the ecosystem (Sabatier *et al.*, 1997). Conversely, there is growing evidence that the composition and structure of artificial mosaics created through different land management

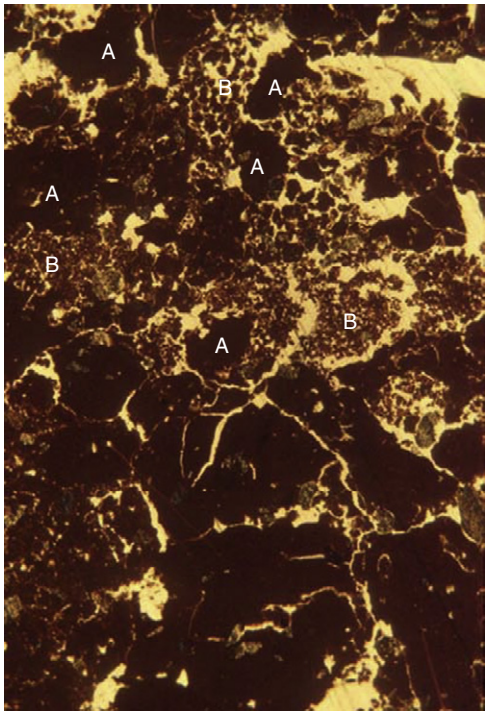

Figure 4 Thin section of a forested oxisol from Central Amazonia (X 0.5) showing accumulation of biogenic structures made by different ecosystem engineers. (a) compact earthworm casts and (b) dispersed pellets of soil deposited in a soil cavity by ants or termites.

practices have effects on biodiversity and the distribution of soil habitats.

Above these five scales there is, of course, the biosphere where all ecosystem services merge. At this global scale, atmospheric composition, temperature conditions, and the dynamics of the ozone layer are determined.

Examples of vertical organizations in soils

Climatic conditions determine the production of biomass by different ecosystems and so may significantly influence the amount and quality of organic matter produced. This, in turn, affects the populations of ecosystem engineers (**Figure 5**).

For example, dry or cold desert soils have no earthworms and the common ecosystem engineers are mainly ants (which have little influence on SOM dynamics) and termites. In such conditions, microbial communities tend to be dominated by fungal components and a discontinuous and relatively modest contribution of soil ecosystem engineers to soil processes (Scales 3 and 4). This gives foodweb control (Scale 2) a predominant role in these systems (Moore *et al.*, 2004).

Following soil and climate natural variations, the set of embedded processes that represent soil function may have different importance and composition. In the same region, different soils – or different types of natural or managed vegetation on a similar soil type – may have rather different species communities. Plant communities typically have a strong effect on the community of soil organisms (De Deyn and Van der Putten, 2005). Forest ecosystems tend to produce litter of a rather low quality and decomposition processes generally rely on communities dominated by fungi and arthropods that decompose the litter *in situ*. Earthworms that bury leaves in soil to stimulate decomposition by bacteria and open the soil structure to allow deeper rooting are often in very low densities in such environments. In contrast, grasslands and pastures are generally more favorable for earthworms, so the overall system shifts from fungi/micro-foodweb/arthropod to earthworm/bacteria-dominated litter decomposition systems. In agriculture, data from many different environments indicate a general depletion of macro-faunal communities when natural vegetation is replaced by managed systems (Lavelle and Spain, 2001).

Communities of ecosystem engineers (plants and invertebrates) organize their functional domains in ecosystem mosaics, which create a diversity of habitats for smaller organism communities in the rhizospheres of different plants (Marschner *et al.*, 1986). The continuous release of readily available substrates into the rhizosphere stimulates a high diversity and abundance of soil biota, especially heterotrophic microorganisms. However, Blackwood and Paul (2003) suggested that this activation selects only fast-growing microorganisms which take advantage of the release of easily decomposed C sources for growth, extract nutrients from the surrounding soil, and release them when they are preyed upon by small predators (Clarholm, 1985). Once completed, this flush of activity diminishes as root tips move away and fine roots die, allowing a different microflora to form in the root litter. Plants are also associated with specific communities of mycorrhizal fungi, which substantially enhance the ability of plants to forage for nutrients and water and protect them from diseases (van der Heijden *et al.*, 1998; Hedlund and Harris, 2012).

Similarly, collembola and acari may have rather different communities inside or outside of patches dominated by a given earthworm population (Loranger *et al.*, 1998). They thereby exert different effects on fungal communities by selectively feeding on their hyphae, or by dispersing their spores.

There is also abundant evidence in the literature that invertebrate ecosystem engineers (earthworms and termites) have similar specific effects within their respective functional domains. For example, intestinal mucus of earthworms, or the saliva of termites, has analogous effects as root exudates in stimulating a specific microflora that digests the ingested organic matter. They then continue their activities for a while in the excreta of these animals and thus become part of the macro-aggregated fraction of soils (Barois and Lavelle, 1986).

Response of Soil Communities to Agricultural Practices and Other Disturbances

Agricultural soil management strongly affects the whole ecosystem as it can change the dominant type of vegetation (forest to grassland or annual crops), the quality and amount of organic inputs (often reduced when plant cover is not continuous and chemical fertilizers are used), and affect some basic soil characteristics, such as pH.

In contrast, it has been shown that changing from tillage to 'no till' agriculture can increase the microbial biomass as well as the ratio of fungal to bacterial biomass (Beare *et al.*, 1997). In this way, it is clear that there can be a significant decrease in

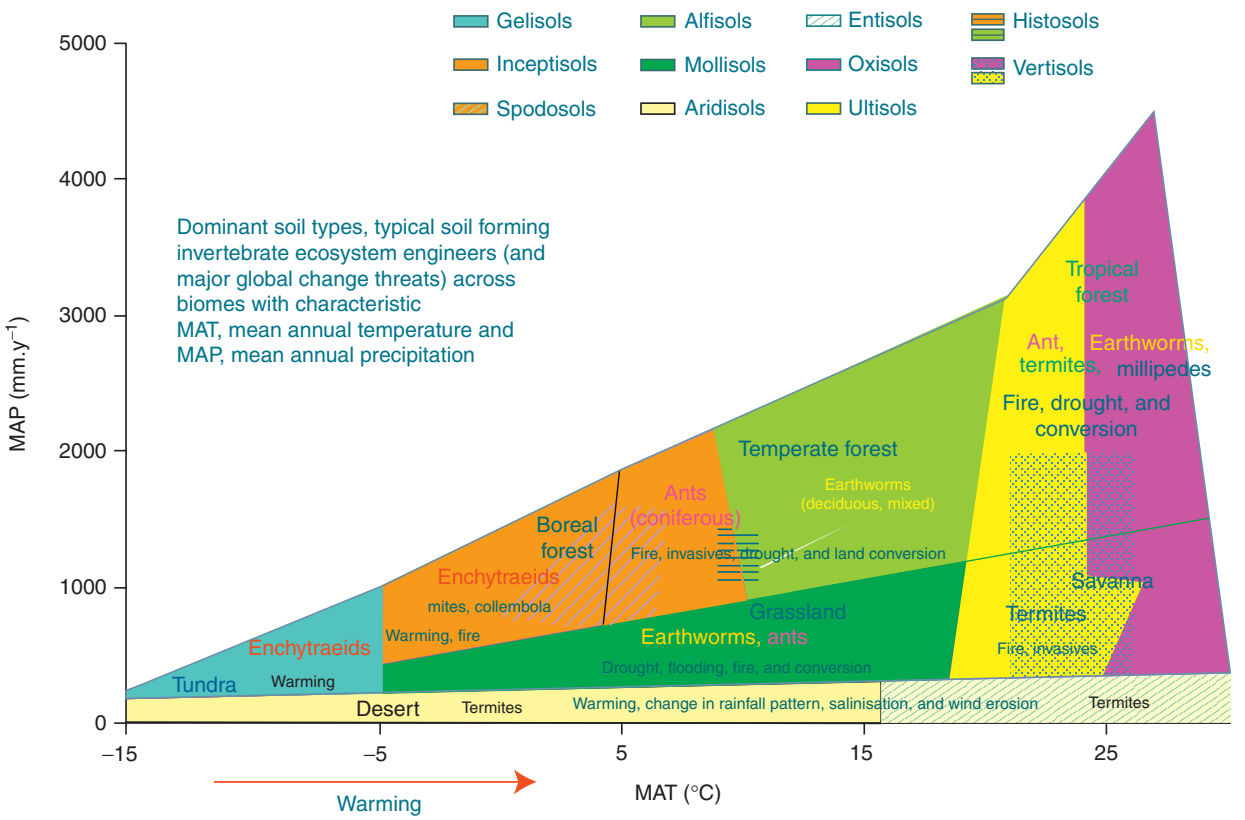

Figure 5 Dominant groups in soil faunal communities across a climate gradient. Reproduced from Brussaard, L., 2012. Ecosystem services provided by the soil biota. In: Wall, D.H., Bardgett, R.D., Behan-Pelletier, V., *et al.* (Eds.), Soil Ecology and Ecosystem Services. Oxford, UK: OUP, pp. 45–58.

functional diversity of microbial communities along a gradient of increasing agricultural intensification (Degens *et al.*, 2000) (**Figure 6**).

T-RFLP and cloning data obtained in representative land use systems in Western Amazonia have shown that diversities of total bacteria, symbiotic nitrogen-fixing bacteria, and arbuscular mycorrhizal fungi are not affected by land use systems (Jesus *et al.*, 2009; Lima *et al.*, 2009; Stürmer and Siqueira, 2011; Leal *et al.*, 2013). However, the relative abundance of these functional groups is affected, probably due to the different rhizosphere characteristics of the various plant communities. However, diversity and density of macro-fauna, like beetles, decrease with land use intensification from forest to pasture (Korasaki *et al.*, 2013). A significant relationship between ecological functions (seed dispersion, dung removal, soil excavation, and abundance of fly larvae/biological control) and the density and diversity of dung beetles was also found, in which the highest diversity of dung beetles was related to an increase in all these functions *in situ* (Braga *et al.*, 2013). Traditional management by local human communities, i.e., shifting cultivation, can even restore diversity to levels larger than those characteristic of the nearby natural vegetation.

Invertebrate communities are all significantly affected by agricultural practices, although to different degrees and in different directions. Some practices, like the establishment of improved pastures with better-performing African grasses, legumes, and liming, enhance their communities, whereas

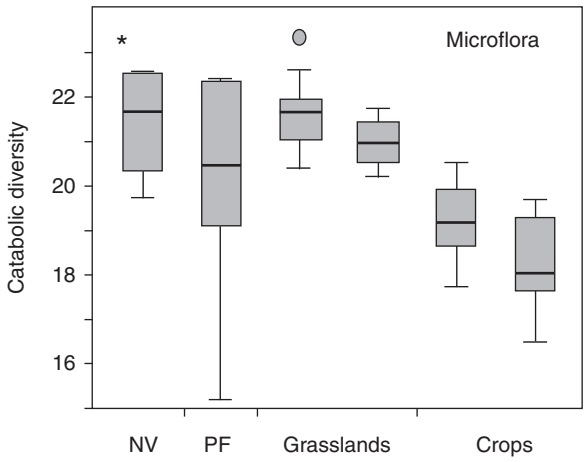

Figure 6 Effects of land use on the functional diversity of soil microflora in New Zealand. others, like traditional annual crops, severely deplete their density and diversity (Lavelle and Pashanasi, 1989; Decaens *et al.*, 1994; **Figure 7**).

European Journal of Soil Biology 30 (4), 157–168.

Biodiversity and Soil Function: Why Maintaining Abundant and Diverse Communities Is Beneficial?

Ecosystem services provided by soils directly depend on the diversity and intensity of biological activities. Although microorganisms mediate more than 90% of all chemical transformations involved in nutrient cycling and the chemical protection of organic matter, the large ecosystem engineers create habitats for the smaller organisms and thus determine soil hydraulic properties. All organisms play important and sometimes very specific roles in sustaining plant production and protecting them from pests and diseases.

Ecosystem Engineers: Soil Structure and Hydraulic Properties

When water infiltrates into the soil, it is either stored for later use by plants or released to recharge aquifers. Soil water status and the balance among these important functions are made possible by soil porosity and the effect of gravity. Porosity is a very complex and dynamic soil attribute that has both a textural and a structural component. Textural porosity is a function of mineral particle size, whereas structural porosity is formed by either physical (e.g., creation of cracks in drying soil) or biological processes, such as bioturbation and burrowing. The latter is what allows vertical and horizontal water flows and plant provisioning.

The literature provides ample illustration of the importance of soil invertebrates and plant roots for the formation of macro- and meso-porosities (Lavelle and Spain, 2001). Subtle balances among soil-dwelling invertebrates that compact and aggregate soil particles and those that decompact and disaggregate these structures determines the size, shape, and organization of the pore space. This balance, which is strongly

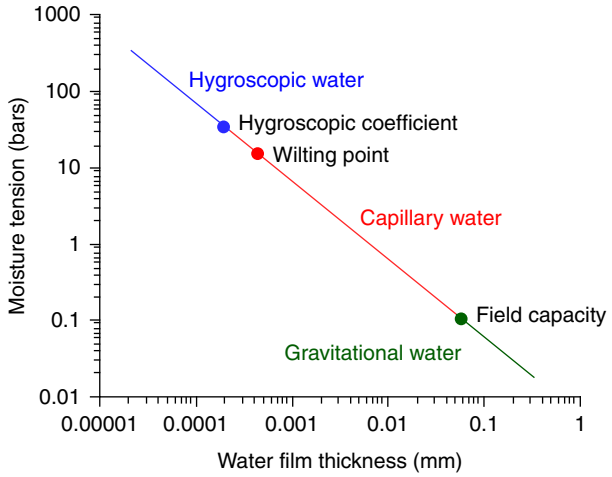

Figure 8 Different kinds of water according to the size of pores within which it is retained.

influenced by plant roots, seems to optimize the permeation of water into the soil by infiltration (in pores > 100 μm), plant provisioning from pores of a size between 0.02 and 6 μm, whereas the transfer of water to deep aquifers and rivers occurs through the largest macropores (Figure 8).

Soil aeration and water dynamics, therefore, largely depend on the activities of ecosystem engineers, which themselves are dependent on a biodiverse ecosystem. Losses of biodiversity may lead to imbalances in the dynamics of pore formation, including, for example, by invasive compacting earthworms (*Pontoscolex corethrurus*) causing severe soil compaction (Chauvel *et al.*, 1999) or the uncontrolled multiplication of surface structures by ants *Camponotus punctulatus*, as in abandoned rice fields in Northeast Argentina (Folgarait, 1998;

Figure 9 Uncontrolled multiplication of mounds created by *Camponotus punctulatus* in Northeast Argentina.

Figure 9). It is evident, therefore, that the diverse activities of soil invertebrate ecosystem engineers are of the utmost importance in agricultural ecosystems, especially those that do not use mechanical tillage.

Decomposition and SOM Dynamics

Decomposition of SOM is the result of two contrasting processes: mineralization and humification. Mineralization allows the release of nutrients contained in dead organic matter into inorganic forms and is important in their uptake by growing organisms, especially plants. Humification is the opposite process and leads to the conservation of organic matter in the ecosystem in protected forms. Protection may occur through chemical processes (by condensation of large-weight molecules or accumulation of undigested compounds) or through physical processes, in which organic elements are protected from microbial attacks within compact aggregates. An important attribute of mineralization is the synchrony in time and space between nutrient release and its uptake by plants and microbial biomass. Synchrony is best achieved in natural ecosystems, within which the combined diversity of decomposing material and decomposer communities allows a fine tuning of the process (Swift and Anderson, 1994; Myers *et al.*, 1994). Agroecosystems most often lose large amounts of nutrients to aquifers and the atmosphere because synchrony is no longer achieved, as in systems that receive excessive chemical fertilizer inputs (Lavelle *et al.*, 2005). Regarding humification, it has recently been argued that the addition of small amounts of easily assimilated organic compounds, like glucose, can allow microorganisms to further assimilate more complex substrates, like cellulose or lignin, and that this can relatively easily release chemical protection (Martin *et al.*, 1992; Fontaine and Barot, 2009). Thus, it would appear that the putative chemical resistance is nothing other than a physical separation of decomposers from their feeding resources. If this assumption is proven it would actually reduce the cases of chemical protection to a very few specific components.

Plant Growth Stimulation and Plant Protection

Sustaining plant production is the third major ecosystem service provided by soils through biological activities. During the course of million of years of coevolution, plants have developed mutualistic relationships with microbes and invertebrates that allow sustained growth and protection from pests and diseases.

Mutualisms with microorganisms

Nitrogen-fixing prokaryotes

Nitrogen is the element required in the largest quantities by plants. The sources of N in soil are: organic matter, usually very low, especially in tropical ecosystems; artificial nitrogen fertilizers, quite expensive and potential pollutants; and biological nitrogen fixation. Biological nitrogen fixation, the conversion of gaseous N_2 into ammonium, is one of the most important functions for the sustainability of life on the planet. Only some groups of bacteria and archaea are able to fix N_2 symbiotically. These prokaryotes can live freely in soil and water or in mutualistic relationships with fungi, lichens, and certain plants. The most important among these relationships are those of rhizobial bacteria with some legumes (Leguminosae). This is due to the economic relevance of many nitrogen-fixing legumes as crops, as well as their widespread occurrence in natural ecosystems. Development of molecular techniques in the last three decades has allowed a significant increase in the knowledge of rhizobial diversity: from the 6 species in a single genus known in 1984 to approximately two hundred species in 12 genera today. The mutualistic relationships between legumes and rhizobial species range from very specific to rather promiscuous. This diversity must be considered in the selection of specific bacterial strains to produce effective inoculum for a given plant species.

Mycorrhizal fungi

Although not required in such large quantities as nitrogen, phosphorus is usually the nutrient element mostly limiting plant growth in tropical ecosystems. The low availability of phosphorus is due to its immobilization through strong chemical fixation on components of weathered soils to form insoluble inorganic calcium, aluminum, and iron phosphates. Phosphorus also has a very low mobility in soil, which further limits its availability.

Mycorrizal fungi can establish mutualistic relationships with the majority of plant species (Read, 1991). Hyphae infect the roots of plants and spread through the soil exploring a soil volume much larger than that which could be explored by the roots alone. They thereby scavenge nutrients such as phosphorus and zinc from sources very distant from the root system. There are seven types of mycorrhizal fungi, but the most important ones are arbuscular or endomycorrhizas and ectomycorrhizas. They also enhance plant resistance to various stresses, such as heavy metal contamination and drought, as well as provide some protection against pathogens.

The use of rhizobial nitrogen fixation by legumes to replace artificial nitrogen fertilizers is an outstanding example of the contribution of biological processes within sustainable agriculture (Sileshi *et al.*, 2008). For example, the inoculation of soybeans in Brazil with selected *Bradyrhizobium* strains completely replaces nitrogen fertilizers, saving billions of US dollars annually. Unfortunately, this practice is virtually restricted to soybean (99%) and only 1% is applied to the bean *Phaseolus vulgaris*.

Plant interactions with invertebrates

Soil invertebrates have well-identified and measured effects on plant growth, some directly through physical conditioning of the soil and others indirectly through protection against pests and diseases or the selection and activation of mutualistic microbial populations. Pot experiments, with or without almost any type of non-pest micro- to macro-fauna, have typically found significant increases in growth/biomass (Setälä and Huhta, 1991; Brown *et al.*, 1999; Scheu, 2003), especially above ground. In addition, below-ground biomass can sometimes be reduced, even under conditions of high nutrient fertility (Lavelle and Spain, 2001).

In the case of earthworms, five mechanisms have been identified that promote a better growth and protection of plants (Brown *et al.*, 2000). They are:

- Enhanced nutrient release in fresh casts that are then subsequently colonized by plant fine roots (Lavelle *et al.*, 1992; Chapuis-Lardy *et al.*, 1998; Decaëns *et al.*, 1999);
- Improved soil physical conditions, which enhance plant water supply;
- Enhanced root mycorrhizal colonization;
- Direct control of plant parasites;
- Production of hormone-like compounds (Blouin *et al.*, 2005).

Conserving Soil Biodiversity in Agroecosystems through Management Options at Different Scales

Soil biodiversity is highly sensitive to human intervention at five scales (**Figure 3**), so good soil and vegetation management is important for its conservation. Large organisms are more sensitive to disturbance than smaller ones, and changes in communities of large organisms can have cascading effects on the communities of smaller organisms.

The organization of the agricultural landscapes (Scale 5) influences the regional pool of biodiversity (β diversity) and possible recolonization of degraded farm land. At the plot/farm scale (Scale 4), soil tillage, irrigation, the use of chemical fertilizers and pesticides, and the configuration of the plant communities all have strong effects on above- and below-ground biodiversities. At the scale of individual plants (Scale 3) and their associated ecosystem engineers, introduction of plants with specific ecological or environmental properties (such as, e.g., those with high N contents in N fixing plants, allelopathic properties for other plants and microbes, strongly anchoring or fine and dense root systems) may be used to manipulate the biodiversity of the meso- and micro-fauna, and the microflora. For example, plant parasitic nematodes can be controlled/regulated by earthworms that create assemblages of soil aggregates and soil pores that are favorable/unfavorable habitats for nematodes (Scale 2). Likewise, microbial supplements can be inoculated into soils to directly modify and enrich microsites with favorable microorganisms (Scale 1).

Scale 5: Landscape

The organization of eco-efficient landscapes that combine satisfactory economic performance with equitable and adequate social development and the conservation or improvement of their natural capital is slowly becoming a priority in rural development (Jackson *et al.*, 2012; Leakey, 2012). This awareness comes from the understanding that most ecosystem services are delivered at the landscape scale rather than at smaller scales. Pollination is a clear example that shows that if natural areas are not conserved close to intensively managed plots, dramatic deficits in pollination will occur (MA, 2005). Conversely, when landscape intensification is associated with a decrease in biodiversity, soil ecosystem services, such as hydrological functions, carbon storage, and nutrient cycling (Lavelle *et al.*, 2014), may be impaired or lost.

Ways to manage landscape composition and structure are still poorly studied and understood (Nelson *et al.*, 2009). However, the total number of patches of different types of land use (e.g., natural forest vs. annual crops) seems to be a determining feature affecting biodiversity and ecosystem services. In a study of deforested areas in Amazonia, the crucial tipping point in the relationship between landscape intensification and biodiversity maintenance corresponded to landscapes with at least 50% of tree cover, 20% of which was natural forest. This ratio may serve as an indicator for restoration projects in degraded landscapes. Landscape structure, however, is also important as exemplified by the creation of biodiversity corridors (Rantalainen *et al.*, 2006). However, such relationships may not be immediate and simple as it now seems that the biodiversity of plants is not necessarily linked with biodiversity of other groups. However, delay may occur between the reconstitution of a desired plant community and the expected levels of soil ecosystem services during the early steps of an adaptive cycle *sensu* (Holling, 2001).

Scale 4: Manipulation at Ecosystem Level in a Crop Plot: Tillage, Rotations

Processes of ecosystem reconstruction at the plot scale are much better understood as this is the scale that has frequently been considered, often almost exclusively, by farmers and agronomists.

At this scale the following four major technical elements should be considered to allow an appropriate management of biodiversity (Cavigelli *et al.*, 2012).

- The nature and diversity of plant cover;
- The need for tillage and soil mechanical preparation;
- Fertilization and protection of plants from pests and diseases;
- Application of organic materials as a way of promoting biological activities.

Plant cover: Structure, composition, and diversity

Although plant diversity in cropped land has considerably decreased since the advent of the Green Revolution (Cavigelli *et al.*, 2012), a large number of studies suggest that appropriate levels of plant diversity may be a prerequisite to conserving the diversity of other organisms and the provision of ecosystem services (ES), even within areas of primary production being the first one to respond to this increased diversity. Relationships among plant diversity, the diversity of other organisms, and the provision of ES, however, are not always clear and the

impacts may not be visible for many years (Hector *et al.*, 1999; Hector, 2002).

In general, agroecosystems that mimic the original system – for example, agroforestry systems in a forest area or an improved pasture in a savanna area – are better at conserving biodiversity than those based on monocultures of annual crops. For example, in the savannas of the Colombian Orinoco, macro-invertebrate communities are greatly enhanced, both in total density and species richness in improved pastures with African grasses (Decaens *et al.*, 1994; **Figure 6**). Under such conditions, annual crops have highly deleterious effects, whereas perennial tree crops do not differ significantly from the original savanna. Similar patterns are observed in rainforest areas where agroforestry systems generally have larger communities of invertebrates than annual crops (Barros *et al.*, 2002).

Some plants directly stimulate organisms (e.g., legumes for biological N fixation), whereas others have more systemic effects at keeping soil covered with their stolons and litter production, upper tree canopy shade, or by sustaining generalist predators that will control pests and make applications of toxic agrochemicals unnecessary (Velasquez *et al.*, 2012; Settle *et al.*, 1996; Leakey, 2014).

Plants affect soil biodiversity through the amount and quality of organic material they contribute to the soil as dead leaves and roots (Vohland and Schroth, 1999; Lavelle *et al.*, 2001). They also have a direct effect on soils through the deposition of root exudates, exfoliation of tip cells, and death of fine roots. In some cases, the addition of particular plant species may greatly enhance, or decrease, specific elements of the soil community. This is the case in the approximately 20 000 species within the family Leguminosae, which produce grains, wood, gums, and green manure and which establish symbioses with N-fixing rhizobial bacteria. These legumes have high N contents ($>3\%$) that can be released during organic matter decomposition, or be transferred to other species by the hyphae of mycorrhizal fungi that form root connections and supply N to other plants. Legumes also enhance earthworm activities, with subsequent effects on soil aggregation and physical properties. For example, in Amazonian pastures that contain *Brachiaria brizantha*, the partial or total substitution by the legume fodder plant *Arachis pintoi* allows earthworm density to significantly increase from 217 to 365 individuals per square meter (68%), with a subsequent 87% increase in the fraction of biogenic aggregates to 25.3% and a 15% decrease in non-macro-aggregated soil. Plant-available water in these soils increased 20%, from 79 to 95 g kg^{-1} (Velasquez *et al.*, 2012).

In contrast, some plants may have intrinsic detrimental effects on soil biota. Particular attention has recently been brought to new cultivars of soybean that no longer favor rhizobial associations and to rice cultivars that do not respond favorably to earthworm or organic matter additions (McCouch, 2004; Noguera *et al.*, 2011).

Polycultures (e.g., agroforestry) with diverse plant community composition have greater rhizosphere diversity than monocultures, as significantly greater amounts of carbon substrates are released by roots. This stimulates greater biodiversity among the invertebrate litter decomposers (Vohland and Schroth, 1999) and primary consumers living close to the root systems. They attract predators and other organisms vital to foodweb functioning. In Africa, the ratio of organism densities in agroforestry systems to conventional farming systems varied from 1 (parasitic nematodes) to 2–3 (nonparasitic nematodes, acari, collembola, ants, and coleoptera), and other ratios were as follows: earthworms (3.1), chilopoda (5.6), and diplopoda (6.1) (Barrios *et al.*, 2012).

Tillage

Tillage and other soil mechanical preparations are a further critical element of agroecosystems that may profoundly influence soil-living communities. The recurrent destruction of soil structure by plowing maintains soils at an early successional stage, according to Holling's (2002) adaptive cycle paradigm. Under such conditions, species that require stable environmental conditions and mutualistic relationships with other organisms for their development are progressively eliminated as negative interactions (competition and predation) prevail. Tillage affects soil biota both directly by killing them and indirectly by decreasing the food resource base and destroying their habitat. This is illustrated by the mortality of large invertebrates and the destruction of fungal networks (Cavigelli *et al.*, 2012) and the significant reduction of earthworm numbers and diversity with its consequent negative impacts on soil physical properties (Wardle, 1995; **Figure 10**).

Similar results have been reported for a variety of soil invertebrates (Marchao *et al.*, 2009) in cropping systems derived from the Cerrado vegetation of Brazil, where, with the exception of termites and ants, most groups benefit from a shift from tillage to 'no-till' systems. Nevertheless, Dominguez *et al.* (2009) reported that no-till systems had a lower population density than the natural grassland (70 individuals per square meter as compared to 297 in the original ecosystem).

Systems with reduced tillage can have higher microbial biomass and higher fungi:bacteria (F:B) ratios (Beare *et al.*, 1997), but recent studies suggest that this is not the general situation. In Laos, for example, in no-till and cover crops systems in tropical grasslands, Lienhard *et al.* (2012) did not find a change in the F:B ratio, although a clear relationship was observed between the density and the quantity of microbial groups and diversity of crop residues (**Figure 11**). Overall genetic diversity of the microbial community showed a different pattern linked to soil chemical parameters, such as soil acidity (exchangeable Al, pH, and CEC) and C:N ratio. Similarly, Strickland and Rousk (2009) had indicated that these results were far from general. However, Helgason *et al.* (2009) did not find that effect of tillage in intensive tilled versus untilled soils of the Great North plains (Beare *et al.*, 2009).

Fertilizers and plant protection

Agrochemicals are yet another element of agroecosystems that impact strongly on soil biodiversity. Some chemicals usually have positive (e.g., liming) or neutral effects (chemical fertilizers), whereas others (most pesticides) are detrimental (**Figure 12**).

Liming reduces soil acidity and generally increases overall biological activity, and there is a trend for the F:B ratio to decline (Rousk *et al.*, 2010). Earthworms respond to this by significantly increasing their biomass (Edwards and Bohlen, 1996; Davidson *et al.*, 2004; Potthoff *et al.*, 2008). In the

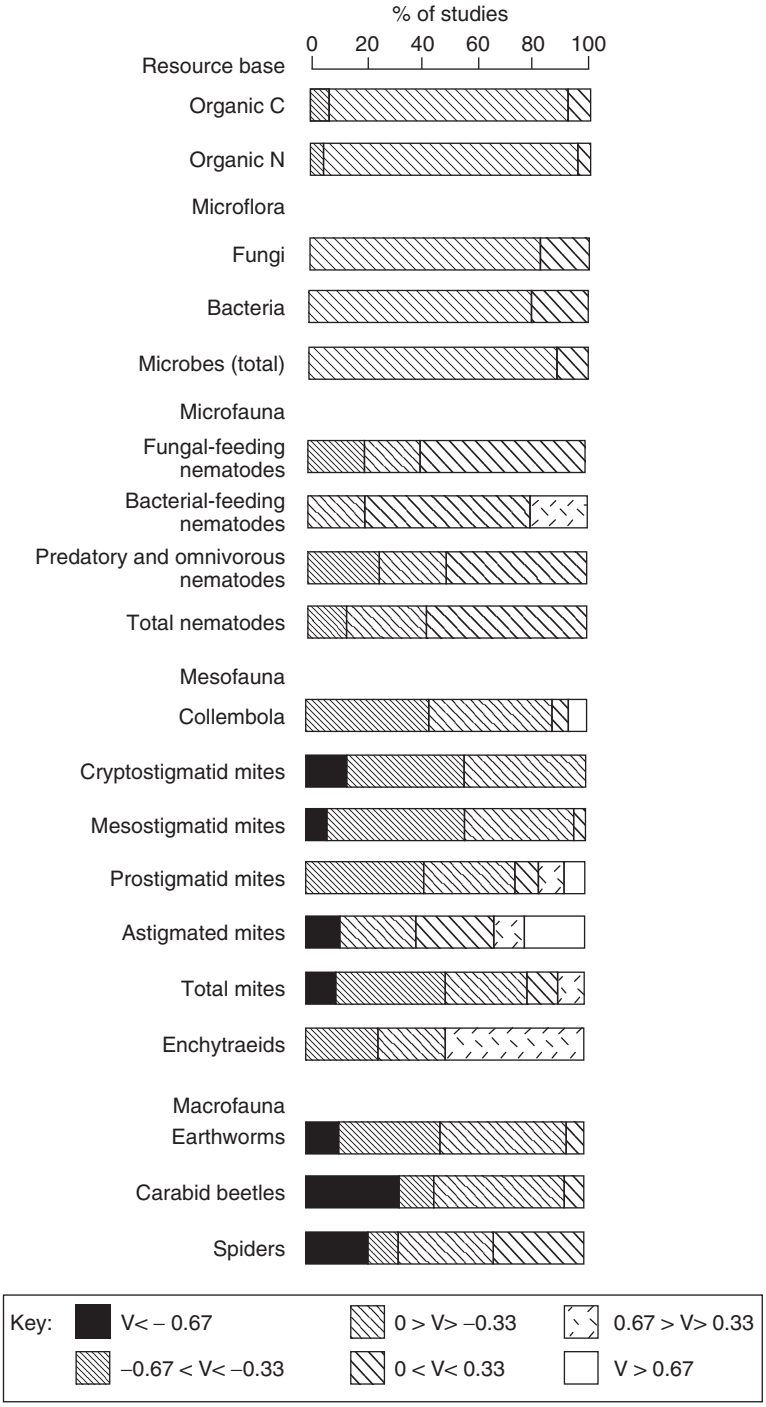

Figure 10 Effect of tillage on abundance or biomass of soil organism populations. V is the ratio of no-till to control tilled systems. Reproduced from Kladivko, E.J., 2001. Tillage systems and soil ecology. Soil and Tillage Research 61, 61–76.

Colombian savannas, the positive effect of exotic pastures (Figure 7) is also a system response to liming and changes in the vegetation cover. However, liming aimed at counteracting the effects of atmospheric acid deposition in forests in Europe did not affect species richness but did significantly decrease macro-invertebrate densities, with contrasting effects on different groups. Although some coleoptera were favoured, the majority of Araneae families (Lithobiidae) and Coleoptera (Staphylinidae) had larger densities in nontreated plots (Auclerc *et al.*, 2012). Part of the observed detrimental effect was related to the increased aluminum toxicity that occurs in some soils when pH is increased (Larssen *et al.*, 1999).

Industrial chemical fertilizers usually do not directly affect soil organisms (Beauregard *et al.*, 2010) but increase plant production. However, the production of certain soil enzymes that are involved in nutrient cycles (e.g., amidase in the

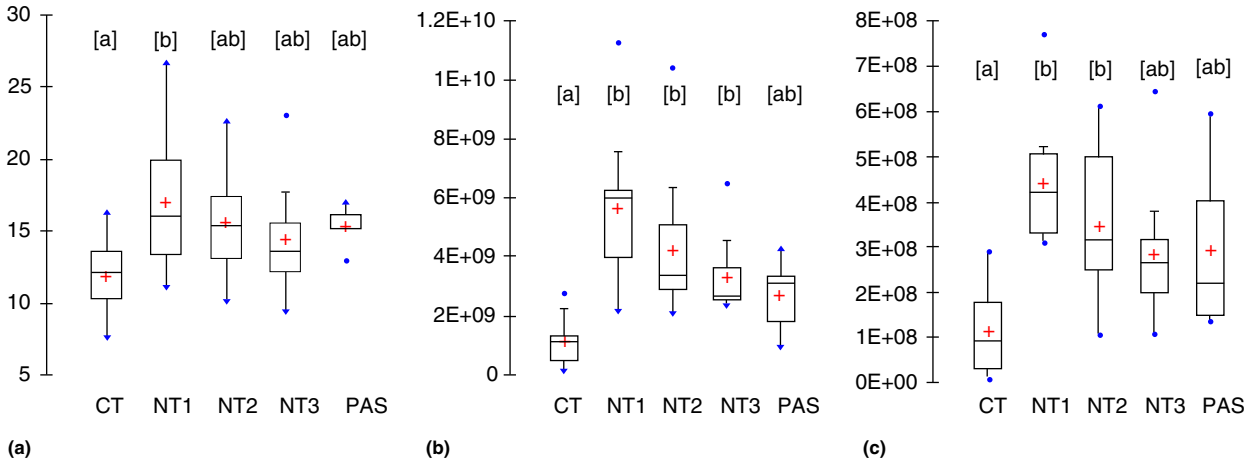

Figure 11 Effect of tillage on microbial diversity in crops from Laos (Lienhardt *et al.*, 2010). Box and whisker representation of (a) molecular biomass (micrograms and per gram of soil), (b) bacterial density (copy of 16S rDNA per gram of soil), and (c) fungal density (copy of 18S rDNA per gram of soil) recorded in natural pasture land (PAS), conventional tillage (CT), and no-till systems (NT (1, 2, and 3)). Letters in brackets indicate significant differences (Kruskal–Wallis test ($P < 0.05$, Bonferroni corrections).

Figure 12 Adult cicada from a gallery forest killed by aerial applications of *Beauveria* in nearby industrial crop fields in the Llanos Orientales region of Colombia (Photo Patrick Lavelle).

nitrogen cycle), which normally releases mineral nutrients, may be significantly depleted (Dick, 1992). Loss of such functions may explain, at least in part, the decrease in production generally observed when shifting from conventional to organic agriculture.

Pesticides are by far the most detrimental agrochemicals with regard to biological activity and biodiversity. However, their wide chemical diversity, the large variation in frequency and quantity of applications, and the resulting soil reactions make generalizations difficult. This is exacerbated by poor assessment methodologies. The literature is also limited and generally focused on one type of pesticide, although it suggests that one-time applications have only small effects in the medium term, because the product is biodegraded, allowing microbial or invertebrate communities to return to pre-application levels within a few weeks (Cavigelli *et al.*, 2012). Repeated applications, however, may lead to more serious and durable changes in soil biology (Stromberger *et al.*, 2005; Larink, 1997; Edwards and Bohlen, 1996). Studies with the herbicide glyphosate indicate few long-term effects on microbial communities and their activities (Kremer and Means, 2009). However, increased susceptibility to fungal diseases (*Fusarium*, *Phytophthora*, and *Pythium* spp.) has been detected. Selection of the most aggressive parasitic nematodes in the presence of pesticides has been also observed (Lavelle *et al.*, 2004). This may perhaps explain why the need for pesticide applications is growing in highly intensive crop systems, especially in the tropics. A special mention should finally be made here of biological insect-control agents (such as the fungus *Beauveria* or *Bacillus thurigiensis*) that have less contaminating effects but still have undesired nontarget effects on non-pest insect populations.

Organic amendments

As a generalization, organic inputs increase the species richness and abundance of soil organisms as compared with conventional cropping systems (Bengtsson *et al.*, 2005; Hole *et al.*, 2005), although in some cases no response has been observed (Cavigelli *et al.*, 2012). This may result from the absence of species that would have benefited from the improved conditions.

A large part of the detrimental effects of intensive agriculture on soil organisms is due to starvation. Although residue inputs are severely decreased by weeding and the exportation of large part of the above-ground plant biomass, the use of chemical fertilizers reduces food sources even more (Lavelle *et al.*, 2004). In contrast, organic agriculture based on diverse materials, such as animal and green manures,

biosolids, biochar, compost, decomposing plant lixiviates, small branches, and other wood residues, provides organisms with beneficial substrates while it increases biomass and plant species diversity, with a wide range of organic inputs (Cavigelli *et al.*, 2012). All this diversity leads to great variation in decomposition, mineralization, and humification, which is further varied by the effects of climate and soil differences at large scales and by invertebrate and microbial communities at smaller scales (Lavelle *et al.*, 1993).

An early consequence of depositing organic matter on the soil surface is the enhancement of communities associated with litter, such as micro-arthropoda, myriapoda, isopoda, and a large number of insects (Ruiz-Camacho *et al.*, 2011). This community participates in the composting of organic residues and their further mineralization by soil microorganisms in the casts of endogeic or anecic earthworms. A common situation following organic inputs is an increase in aggregation and aeration leading to improved soil physical structure through the enhanced activities of ecosystem engineers (Lavelle *et al.*, 1997).

Another interesting function of organic inputs is the maintenance of dense invertebrate populations that provide food for generalist predators which can switch to any invertebrate pests emerging on crops, thereby providing an element of biological control (Settle *et al.*, 1996). However, there are significantly different effects of different types of organic materials on soil macro-fauna. In a study involving 13 cereal crops, 4 pastures, and 5 forests conducted on similar soils of the Bassin Parisien region of France, Ruiz *et al.* (2011) found significant differences in the biodiversity, abundance, and species composition of macro-invertebrate communities depending on the quality of the organic inputs. A mixed compost of sewage sludge, green manure, and urban solid waste compost did not greatly increase either the total density or biodiversity over that of conventional cropping plots. However, a mixture of farm yard manure, liquid compost of green waste, and the organic fraction of municipal solid waste compost increased the total abundance of macro-invertebrates up to fourfold. However, total species richness per sample did not vary much except in one direct-drilled system with a winter cover crop in which species richness more than doubled and reached similar values to those of nearby forest sites.

Scale 3: Manipulation of Populations of Ecosystem Engineers: Plants and Invertebrates

Increases in the density of beneficial organisms are often sought through the direct inoculation of plants, invertebrates, or microorganisms. The aim is to enhance ecosystem engineering in its physical, chemical, and biological dimensions.

However, these inoculated organisms will survive only if suitable conditions for their activities occur. These include adequate moisture and temperature, appropriate soil pH and nutrient status, and sufficient organic matter quality and quantity (Lavelle *et al.*, 1993).

As is the case in agroecosystems managed by tillage or the use of agrochemicals, plant communities are relatively easy to manipulate, so long as natural competing communities are suppressed or eliminated. The use of other plants integrated into farming systems as companion crops to provide ecological/environmental goods and services is also widely implemented to enhance production. Some introduced species have physical roles, forming erosion-control barriers or windbreaks, whereas others may be N-fixing legumes included for soil fertility management. Such plants may be so effective that N fixed in these artificial systems is equal to 1.5 times N fixed in natural ecosystems (Lavelle *et al.*, 2005; MA, 2005). Other plants may be used as traps for pests, especially phytoparasitic nematodes, parasitic weeds like *Striga*, and cereal stem borers (Khan *et al.*, 2007; Cook *et al.*, 2007).

Inoculation of earthworms has been widely practiced to improve exotic grass pastures in New Zealand (Edwards and Bohlen, 1996). Likewise, earthworm inoculation has been used as part of the FBO (Fertilization Bio Organique) patented technology (Senapati *et al.*, 1999) in which earthworms are inoculated into trenches where the highly organic conditions create small islands of favorable soil functionality (Brown *et al.*, 1999). Interestingly, in addition to occasional spectacular increases in production, this technology also improved the organoleptic quality of tea from plantations in India and China by 15–30%.

Scale 1: Manipulation of Microbial Communities

Microorganisms, such as N-fixing bacteria, plant growth promoters that release growth phytohormones in soil, bacteria that protect plants from fungal (*Fusarium* and *Phytophthora*) diseases (*Pseudomonas* spp. and *Trichoderma*), and fungi that feed on phytoparasitic nematodes, are by far the most frequently used organisms for agroecological manipulations. Soil microbial communities, however, occupy specific microsites in soil, built by ecosystem engineers (macro-invertebrates and roots). They are, furthermore, subject to predation from micropredators and to competition with other microbial colonies (Lavelle and Spain, 2001). This particular ecological circumstance is a substantial obstacle to microorganism inoculation in soils because before they reach the expected target (e.g., a root) they may be preyed upon by any element of the predator micro-fauna, be lost in a micropore where no root will penetrate for months, or be eliminated by more competitive microorganisms even if they arrive at the right site.

Because these conditions are not taken into consideration or, as often so, not really understood, inoculation may only be effective when careful inoculation techniques are implemented.

In a survey of 62 preparations available in SSA Africa, Jefwa *et al.* (2013) found no effect at all in 95% of cases. Of the 31 products tested, only 42% of those claimed to contain Rhizobia actually contained the expected strain, with no contaminant, whereas 34% only had contaminants. In total, for the 62 preparations, 54 strains of bacterial nonrhizobial products of the 147 announced and 26 of 73 mycorrhizal products had the expected strain. Of 13 preparations referred to as mycorrhizal inoculants, only three had a substantial effect under laboratory conditions, although seven had smaller than expected; the remaining three preparations produced no colonization at all. Of 37 bacterial strains not supposed to be present in these preparations, eight had potentially severely

harmful effects for human health and one for plants. Out of 18 nonbacterial preparations, only 33% increased maize growth, whereas in soybean only 22% of tested products were effective (Jefwa *et al.*, 2013).

However, many countries have developed legislative frameworks to control the quality and efficiency of inoculants and a large proportion of the products are delivered with detailed instructions for an efficient use.

Future Research in Soil Biodiversity

A large number of studies have shown the importance of conserving and managing biological activities within agriculture and at the same time have indicated that the soil biota is a vulnerable resource. To better use and protect this essential resource, research efforts must continue, with special emphasis on (1) the determination of effective indicators and (2) development of techniques for conserving and using soil biodiversity.

Indicators

The need for indicators: Synthesis of existing approaches and a proposal for establishing a unique set of tools with ISO labeling

A large and diverse number of biological, chemical, physical, and synthetic indicators of soil quality and ecosystem services have been proposed in the literature (Turbé *et al.*, 2010). However, a comparative analysis of the respective advantages and disadvantages of these indicators is needed before testing.

Conservation of biodiversity and manipulation of communities to improve the provision of soil ecosystem services must be considered across all scales simultaneously

This article has shown the vulnerability of soil biological components and the difficulty of managing them properly. This follows directly from the inherent complexity of biological interactions in soils and the imperfect understanding. To improve this understanding and enhance the potential for ecological manipulations at different scales, research should focus on the following:

Scale 1: Microbial inoculants

In situ field tests of survival and development of the inoculated populations are necessary to determine the range of conditions for the use of these microbial inoculants and to provide quantitative estimates of the benefits obtained in the short and longer term.

Scale 2: Control of plant-parasitic nematodes

Determine how to enhance the biodiversity of parasite communities for ecosystem level control through earthworm activities. Of particular importance is assessment of the density and distribution of microsites in which micro-foodweb processes occur and analysis of their impacts on microbial communities.

Scale 3: Earthworm inoculation, service plants, and ants and termites

There is a need to better understand the internal mechanisms affecting the specific interactions that operate between plants and invertebrate ecosystem engineers. This is especially so of the interactions among the different functional domains derived from the activities of different groups of ecosystem engineers, their precise geography in soil, and their successional processes. In addition, the potential to modify the expression of resistance genes in plants should be further explored.

Together, the outputs of such research could lead to better disease control and an enhanced delivery of ecological services from soil biodiversity.

Scale 4: OM applications and biological control

With regard to the determination of appropriate sources of OM for nutrient release, plant protection, C sequestration, biodiversity enhancement, and on-farm production of OM inputs, there is a need to investigate the effects of soil OM quality on nutrient availability, water retention, and carbon sequestration, especially with regard to the activity of soil engineers.

Scale 5: Ecoefficient landscapes

There is now growing evidence that biodiversity conservation and critical ecosystem services, such as pollination, pest and disease control, decontamination, water infiltration, and supply to plants, need to be delivered at landscape scale. There is consequently a need to improve the design of landscapes for enhanced function through such means as biodiversity corridors and the creation of more natural ecosystems within which natural resource capital, such as trees and conserved water bodies, meets the needs of humanity and the environment. Further natural principles to be included are recycling and composting of organic waste using vermiculture and related techniques.

Conclusion

The conservation and management of soil biodiversity is central to the attainment of agriculture that is productive and sustainable over long periods. From this, it follows that greater effort is now needed to maximize the benefits flowing from a wise and conservative use of natural capital. This particularly applies to the soil taht has become seriously degraded both in fertility and agroecological function and is responsible for the declining productivity that is the main cause of the nutritional insecurity and poverty prevalent in many developing countries (Leakey, 2012). Urgent tasks are, therefore, to prevent further resource degradation by maintaining diverse soil covers and adding organic inputs to the soils. Ultimately, a better understanding of ecological processes is required, including the improved, naturally based management of pests and diseases. This, together with a reduction in pollution, is necessary to reverse declining fertility and improve crop yields in ways that have much improved environmental and social consequences for local people, as well as the global community. Once understood, these mechanisms should be urgently

integrated and enhanced in the next generation of agricultural systems to promote greater agricultural productivity and ecosystem conservation.

Biosecurity and Equine Infectious Diseases

MC Roberts, North Carolina State University, Raleigh, NC, USA

© 2014 Elsevier Inc. All rights reserved.

Glossary

Biosecurity All hygienic practices (measures) designed to prevent the occurrence of infectious disease.

Equine herpesvirus 1 neurological disease (Equine herpes myeloencephalopathy, EHM) It is rare in the horse population but apparently increasing in incidence now occurring as outbreaks rather than as individual cases.

Infectious disease Pathogens spread easily from subject to subject either directly or indirectly; in general the index subject has the disease but may be a carrier.

Methicillin-resistant *Staphylococcus aureus* (MRSA) An emerging pathogen of the horse particularly associated with wounds and surgical site infections.

Neurological disease A condition affecting the nervous system control over motor and sensory functions producing a deficit.

Strangles A condition caused by *Streptococcus equi* subspecies *equi*, an unusual inhabitant of the horse's upper respiratory tract, can occur as outbreaks or affect individuals in closed herds through contact with carriers.

Zoonotic disease A disease that can be spread directly from animals to humans or from humans to animals.

Introduction

Infectious diseases are a constant threat to the health and welfare of horses. Several diseases have assumed greater importance as the performance and pleasure horse populations and equine activities have increased and there are new owners who do not understand the implications of equine infectious disease outbreaks to their animals. In addition, emerging diseases have beset the equine species in recent years in North America. Firstly, the introduction of the Old World West Nile virus to a susceptible population has made the the virus to be considered as endemic. Secondly, the change in the antigenicity of equine herpesvirus-1 (EHV-1) to induce a more aggressive form of neurological disease may affect clusters of horses than the field strain encountered previously. Fortunately, North America has been spared the infection caused by the paramyxovirus responsible for Hendra virus infection spread by flying foxes (bats), which is a zoonotic disease and a deadly infection of horses in Australia. However, other infectious diseases are more likely to emerge among horses in North America in the next decade as pathogens and vectors move into and become accustomed to new climate zones. The threat of emergent diseases is apparent in the UK, where a warming climate could precipitate a northward spread of those *Culicoides* spp. responsible for African horse sickness among a highly susceptible population.

Vaccination and preventive management procedures are critical to disease prevention, but these need to be more widely adopted, complied with, and promulgated. The National Animal Health Monitoring System (1998) survey raised the specter that a significant number of horses throughout the United States do not receive regular vaccinations and preventive health is not part of the owners' protocol. Therefore, much work remains to be done in communicating the message before a devastating outbreak of infectious disease among horses takes hold. Unfortunately, vaccines are unavailable or are inefficient for several infectious diseases in the United States. Successful vaccines to protect against equine herpes myeloencephalopathy (EHM) and equine strangles are awaited.

The list of infectious diseases, and the pathogens involved, considered as real or potential threats or concerns in the United States by veterinarians, technicians, and horse owners continues to expand. Some are emerging or emergent diseases (E). Other infectious diseases are potential zoonotic diseases (Z), spread from horses to humans or vice versa (Table 1).

This article provides an overview of biosecurity measures that apply to all potential pathogens with an emphasis on the principles learned from the threat of EHV-1 myeloencephalopathy (an emergent disease), MRSA (a zoonotic disease), and strangles, an infectious disease of historical record that remains a scourge to susceptible horses. The emphasis is on examples from the United States, although the principles of biosecurity are applicable elsewhere.

Much has been written in the veterinary, equine, and lay press on biosecurity matters and the threat of equine infectious diseases getting out of hand. The threat is still real. The human race lurches from one crisis to the next having eluded the bullet without learning from its errors. Biosecurity is much cheaper than dealing with actual infectious disease in any species. The importance of hand washing, the preeminent biosecurity measure, is a major factor why nosocomial infections with MRSA and *C. difficile* are such hazards to patients in human hospitals. The healthcare workers do not routinely wash their hands between patients. What has one learned?

Biosecurity

Biosecurity represents an important part of the veterinarian's responsibilities in the clinic or practice facility, at farms, stables, barns, and at shows and events, where horses commingle from multiple locations. Technicians, owners, and caretakers must understand the implications, share the responsibilities, and implement specific management procedures. Communication with and education of all personnel

Table 1 List of infectious diseases of horses

Viral

- Equine coronavirus
- EHV-1 respiratory disease
- EHV-1 neurological disease (EHM) (E)
- EHV-4 respiratory disease
- Equine influenza
- West Nile virus (Z not by horses) (E)
- Vesicular stomatitis virus (multiple species)
- Equine viral arteritis
- Rabies (Z)
- Eastern/Western equine encephalitis (Z not by horse)
- Equine infectious anemia

Foreign animal diseases (viral)

- Venezuelan equine encephalitis (Z)
- Japanese encephalitis (Z not by horse)
- African horse sickness
- Hendra virus (Z)

Bacterial

- *Salmonella* sp. (Z)
- Strangles (*Streptococcus equi* var *equi*)
- Contagious equine metritis (*Taylorella equigenitalis)*
- Methicillin-resistant *Staphylococcus aureus* (MRSA) (Z) (E)
- *Leptospira* sp. (some serovars are Z)
- *Clostridium difficile* (Z)
- *Clostridium perfringens*
- *Lawsonia intracellularis*
- *Rhodococcus equi*

Foreign animal disease (bacterial)

- Glanders (*Pseudomonas mallei*) (Z)

Protozoal (Tick borne)

- Equine piroplasmosis (babesioisis)
- Potomac horse fever (*Neorickettsia risticii*)
- Lyme Disease (*Borrelia burgdorferi*)

on infectious disease control measures is vital. This is before an outbreak happens and subsequently at regular intervals. Technicians must be empowered to enforce the codes of practice. They are a constant presence at the facility and integral to sustaining biosecurity procedures.

Biosecurity includes all hygienic practices designed to prevent the occurrence of infectious diseases, for example, preventing the introduction of infectious agents, controlling the spread within populations or facilities, and the containment or disinfection of infectious materials. Biosecurity is affected by the ecology of animal and human populations, the biological nature of infectious agents, and the management actions affecting interaction between host and agent. Rigorous hand hygiene is an important part of effective biosecurity and is emphaisized throughout this article.

Preparedness is the Key to Biosecurity

A plan of action to manage equine infectious disease outbreaks should be in place before the onset of clinical disease based on the evaluations of risk assessment, resource management, and horse management. All personnel must be familiar with and preferably certified on the infectious disease protocol for the premises. Risk assessment is the knowledge of ongoing disease outbreaks elsewhere and the potential for their spread. Resource management includes devising and establishing a chain of command with defined responsibilities, for example, to identify isolation and biosecurity capabilities both on- and off-site; to insure the availability of diagnostic sampling materials, disinfectants, and biocontainment materials; and to inspect facilities recently vacated after another equine or livestock event for adequate sanitation (decontamination) and waste removal before animals are readmitted (this includes transport vehicles and trailers/vans). Horse management involves publicizing and enforcing health requirements for access to the facility and implementing an equine identification and tracking system.

If an infectious disease is suspected, the veterinarian must make decisions and assume responsibilities according to the devised plan. The clinician should communicate to all individuals (key personnel, technicians, and owners at the premises) the established plan and indicate that diagnostic testing is valuable but can take time. The clinician must think biosecurity by not making the situation worse, for example, avoid rushing into a barn/stall without having a plan to leave it and must respond to the 'worst-case scenario' until a diagnosis is made.

In the case of a positive (suspect) diagnosis, management procedures based on disease-specific guidelines must be adopted. If there is no diagnosis, biosecurity measures must be maintained for a minimum of 21–28 days after the last case had developed, the differential diagnosis list must be expanded, and infectious disease experts and state health officials must be contacted.

Biosecurity measures have assumed a much greater level of significance based on the experiences gained by many veterinarians and support personnel engaged in managing outbreaks of life-threatening equine salmonellosis mainly in referral hospitals and, more recently, neurological disease associated with EHM at racetracks, showgrounds with large horse populations, and tertiary referral hospitals. Most tertiary referral hospitals, particularly those at universities, have infectious disease control policies and procedures for horses and other species that are updated regularly. Infectious disease control strategies (policies and procedures) should be developed for private practices (and individual equine operations) to cover on-site horse health admissions, accommodation, patterns of personnel and animal traffic on-site, disinfection, waste management, and off-site farm/stable/barn precautions by veterinarians and other personnel.

Biosecurity is only as effective as the acceptance of and compliance with regulations by all personnel, for example, the equine influenza outbreak that emanated from a quarantine center in Australia. Moreover, biosecurity measures however well developed and accepted cannot be taken for granted, for example, spread of foot-and-mouth disease virus from Pirbright, England (foot-and-mouth disease virus World Reference Laboratory) on the tires of contractors' vehicles.

Biosecurity Measures to Limit Infectious Disease Spread

Biosecuity for the technician at a veterinary practice and for the horse owner or caretaker is critical to managing the introduction of an infectious agent. The most common means of spread is through the introduction of a new horse, particularly a horse that is returned from a hospital to a property. New horses should be isolated from the resident population for a minimum of 14 days, ideally for 30 days. Clinical condition and temperature should be monitored daily. Supplies should be separated. The recent arrival should be attended to last. Manure and bedding should not be spread on the fields. Hand washing in running water with soap after handling horses (waterless hand foams or gels if no running water) should be mandatory even if gloves have been worn.

Vaccination is not 100% preventive but is critical to control an infectious disease as exposure is unlikely to be prevented. Vaccination decreases the severity of clinical disease and serves to increase resistance against certain diseases in individual horses and in horse populations.

Quarantine is an important aspect of implementing biosecurity measures. Ideally, there should be a separate facility used for any horse that has left the premises for showing or breeding (commingling) and not just for sick or new horses.

Technicians and handlers should initiate a traffic pattern, wear disposable gloves, booties, and barrier clothing with at-risk and sick horses, and practice the procedure for removing protective gear (without further contamination). Cleaning and disinfection frequency should be enhanced during an outbreak and hand hygiene is crucial.

Visitors should be restricted to one entrance and exit. Vehicle tires and visitor's shoes should be disinfected and footbaths and overboots must be provided. Records of visitors and their horse contact must be kept.

It is critical to be vigilant away from the horse premises (e.g., avoid direct contact with a diseased horse at an event or activity and do not touch horses' noses going down the line from stall to stall) and follow a specific biosecurity procedure on returning.

Biosecurity requires common sense and the ability to communicate clearly. The mantra is to adopt precautionary measures to include waste management, cleaning and disinfection, environmental control, and storage and use of equipment and supplies. Biosecurity plans for any horse facility are never completed. They may be patterned by a particular outbreak and should be reevaluated and updated regularly.

Equine Herpesvirus-1 Neurological Disease

EHV-1, a ubiquitous virus among horses, was occasionally responsible for neurological disease. However, when groups of horses became affected by a neurological disease at the same time, diagnostic results showed the agent to be a variant of EHV-1, prompting the adoption of strict biosecurity measures. Much was learned in a short time frame. Increased risk for exposure in recent US outbreaks included commercial shipping with horses collected from multiple sites and venues, such as quarantine stations, rest farms and stops, veterinary clinics, race tracks, polo events, and hunter/jumper dressage shows, and movement of animals before the disease is recognized. Other important risk factors involved recent exposure to sick horses, including those having increased rectal temperature without evidence of recent surgery, vaccination, or other medical condition associated with fever, and recent exposure to horses that have acute neurological signs, especially if a noninfectious cause has been ruled out.

EHVs are major equine pathogens. There are nine EHVs, not all are associated with overt clinical problems. EHV-1 and EHV-4 are α-herpes viruses transmitted by the respiratory route, infect the upper respiratory tract epithelium, and are the most common.

EHV-1 myeloencephalopathy (EHM) is not a new disease; however, neurological disease associated with EHV-1 (causing EHM) appears to be increasing in incidence in the United States and Europe, although it remains a relatively rare disease in the horse population. Outbreaks of EHM have occurred among pleasure horses and racehorses, show jumpers, horses referred to tertiary clinics, and quarter horses at a cutting horse show. This disease has had significant economic and equine activity impacts. Some racetracks ordered quarantine for several weeks for thousands of horses sent to compete after multiple cases of EHV-1 causing neurological disease occurred, resulting in deaths of several horses. Shows were canceled in many Western states and interstate movement of horses was restricted after the cutting horse event. Some tertiary referral centers have imposed strict quarantine protocols after clinical cases of EHM were confirmed at their facilities.

EHV-1 is highly contagious and is a serious concern and threat to those involved with horse shows, events, farms, auctions, and clinics with a high volume of horse traffic. Certain strains of EHV-1 that affect the central nervous system have resulted in outbreaks of EHM with high morbidity and case fatality. Horses with neurological signs have large viral loads in their blood and nasal secretions. The incubation period is highly variable depending on the host, pathogen, and the environment (including stress) and ranges from 1 to 12 days but often 1 to 3 days. Once sick, the horse can shed the virus and be a source of infection for 7–10 days and for up to 28 days in some instances. Horses can be clinically normal and still shed the virus.

The virus may be disseminated by nasal and respiratory secretions for up to 11 m (35 feet) (animals should be separated by 300 feet) and can survive a wide temperature range (surviving 3–4 weeks in the environment without a host). Transmission can occur directly by nose-to-nose contact and indirectly by vectors, contaminated hands, shoes, clothing and equipment, inanimate objects, such as water buckets, brushes, bits, clippers, etc., and aborted placenta and fetal tissues.

Clinical signs of EHV-1 infection vary from mild respiratory disease to severe EHM. Neurological signs are generally, although not exclusively associated with a recent history of pyrexia, respiratory disease, or abortion in the affected animal or more likely a herd mate. Respiratory signs may be minimal and of short duration. Increased rectal temperature may be the only clinical sign. There may be two fever spikes – an initial temperature rise that is usually mild (101.5–102.5), and transient for up to 4–5 days, and may be missed; the horse may remain clinically normal or develop respiratory disease

with signs of nasal discharge, an increased temperature (>102.5), and coughing. The second wave starts between days 5 and 7 and can continue until day 10 coinciding with the viremia. Infected pregnant mares may spontaneously abort within a week to several months of being exposed, although the mares may have shown only limited initial signs. Other signs include scrotal edema and loss of libido in stallions, uveitis, dependent and facial edema in adults, nasal discharge, and pneumonia in young foals.

Neurological Signs

Expression of clinical signs in the relatively small number of EHM cases is a consequence of vasculitis followed by hemorrhage, thrombosis, hypoxia, and secondary ischemic degeneration in the central nervous system.

Signs include progressive or acute onset ataxia (incoordination) or recumbency approximately 1 week after viral exposure that affects a single animal or group of at least 2 years of age. Signs may progress rapidly over 24–48 h. Pyrexia and depression are usually noted 3–4 days before the onset of neurological signs, which include pelvic limb ataxia, paresis, or paralysis and may affect all four limbs. Signs are usually more severe in the pelvic limbs than in the thoracic limbs and may lateralize. There may be signs consistent with lower motor neuron dysfunction, urinary incontinence, reduced tail tone, penile or vulval flaccidity, and loss of perineal sensation. Tetraplegia and death may supervene. Paralysis and recumbency carry an increasingly poor prognosis. Horses rarely show abnormal mentation or develop cranial nerve signs. Most horses exhibit mild to moderate neurological signs and stabilize rapidly becoming normal 3–6 months after onset of clinical signs, although residual deficits may persist.

EHV infections are ubiquitous. Most animals are infected during the first year of life. The pathogen is latent. Up to 80% of horses (possibly more) are purported to be latently infected with EHV-1 or EHV-4, cannot easily be identified, and serve as important reservoirs.

EHM outbreaks have occurred in late fall through late spring, possibly coinciding with pregnancy and lactation associated with abortigenic EHV-1 in mares and respiratory EHV-4 transmission among foals. EHM outbreaks may be dependent on the reactivation of latent EHV-1, EHV-4, or both viruses on introducing a new animal into a population and associated stress. EHV-1 (and possibly EHV-4) can remain latent for the horse's entire life. Under stress conditions, the virus may replicate and is shed in nasal secretions. Other horses can be exposed and infected without necessarily the shedder becoming ill. Outbreaks may represent new infections with a virulent strain that occurs in a large number of horses over a short period of time.

Immunology

High virus-neutralizing titers (humoral immune response) are detected within a few days of the onset of neurological signs. However, there is no correlation between the level of serum antibody titers and virus protection. Viremia occurs in the presence of neutralizing antibodies, as apparent in vaccinated or naturally immune horses. Cellular immunity is critical and complex and plays an important role in clearing EHV-1 leukocyte-associated viremia. EHV-1 exhibits similarities with many herpes viruses and may be capable of modulating (evading) the horse's immune response.

Therapy

Supportive therapy may be needed for several weeks to months and includes slinging the horse if it is weak in the pelvic limbs or is recumbent. Ataxic horses that remain standing may be better on a (firm) ground surface than in a stall. Use of nonsteroidal anti-inflammatory drugs), such as flunixin meglumine, makes the patient feel better, and the antiherpesvirus drugs widely used in human patients, acyclovir and valocyclovir, may be beneficial early in the course of the disease or prophylactically.

Prognosis

Many horses stabilize and recover completely in weeks to months. Some retain residual neurological deficits. The prognosis is worse if the horse is recumbent in the first 24 h.

Prevention

Efficacy of EHV-1 vaccines is questionable and randomized controlled studies are lacking. Vaccine products provide varying levels of protection against respiratory disease (modified live virus (MLV) and killed) and abortion (killed and some MLV). Anecdotal evidence suggests that vaccination may offer reasonable protection against a flare up of respiratory disease (although few data exist). Protection against abortion is less clear as the prevalence is extremely low. Current EHV-1, EHV-4, or EHV-1/4 vaccines are not effective against the neurological disease. At best the vaccinated horse that develops neurological disease will shed fewer virus particles and be less likely to spread the disease to other horses. There is evidence of an association between neurological disease and recent and regular vaccinations with mono- or bivalent killed vaccines.

On premises with confirmed EHM, exposed horses should not receive booster vaccinations. However, the immune status of nonexposed horses and those that must enter the premises if not vaccinated against EHV-1 within the past 60 days should be enhanced by booster vaccination. The reduced nasal shedding of infectious EHV-1 by recently vaccinated horses may indirectly help to protect other horses by reducing the dose of exposed virus.

Regulations

State animal health officials provide information on enhanced requirements in the face of an outbreak.

Several states require reporting of EHV-1 (known as EHM) and quarantine of affected and in-contact horses.

Clinical Outcomes

Clinical outcomes in EHM outbreaks are modulated by many risk factors, including the host immune system (vaccination,

cytotoxic T-lymphocytes, and major histocompatability complex), stress (lactation, double infections, and racing), and the genetic characteristics of virus isolates. The proportion of animals showing neurological signs when infected with the neuropathic strain varies with each outbreak. Neurological diseases outbreaks are relatively rare compared with non-neurological disease outbreaks, suggesting that the majority of EHV-1 strains encode the nonneuropathic strain.

Diagnostic Testing

Identification of the pathogen requires nasal swab (shedding may be of short duration) and whole blood sample (for buffy coat) at the onset of clinical signs (temperature). Polymerase chain reaction provides the most rapid testing. Real-time polymerase chain reaction (RT-PCR) assays are used to detect and differentiate neuropathic from nonneuropathic EHV-1 strains.

RT-PCR assays detect only viral genomic deoxyribonucleic acid in the specimens tested and are unable to distinguish between lytic, dead, or latent virus and do not predict clinical outcome. Interpretation of PCR viral detection for EHV-1 should be done only in the context of the presenting signs for disease in the horse being tested. The significance of a positive PCR in an asymptomatic horse is unknown.

Horses with high fevers and signs of coughing or mild nasal discharge, with or without neurological deficits, should be tested for EHV-1 by PCR diagnostics if there are no other explanations for their signs of disease. Detection of a positive PCR for EHV-1 in such instances should warrant isolation and limited movement of exposed horses.

Management of Outbreaks of Neurological Disease Associated with EHV-1

If the horse is at high risk for exposure, primary security measures must be implemented to include stopping any horse movement at the event or hospital, confining the horse to a stall or moving immediately to a separate facility and placing all horses with clinical signs in this area. Disease surveillance must be introduced by taking and recording rectal temperature twice daily, having the owner/caretaker/technician contact the veterinarian immediately if findings are abnormal, and having the veterinarian perform a physical examination on suspect horses and initiating clinical and diagnostic testing. Access must be limited to essential personnel, veterinarians, technicians, and caretakers who should receive training in and follow biosecurity protocols.

Once a positive horse is identified, either state or voluntary quarantine must be imposed for 21 days after the last clinical sign (usually the temperature rise), although quarantine may last at least 28 days. Recommended exit (discharge) requirements include testing negative for EHV-1 shedding from the nasal cavity and no virus detected in blood.

It is vital to identify and implement a secondary perimeter to allow horses to be exercised and enable limited continuation of internal organized activities. This could be the entire facility, venue, or township. All animals within the secondary perimeter are considered free of infection but at increased risk of exposure and development of disease. Enhanced surveillance is critical. Horses can travel only from outside of this facility and are under the regulation of the veterinarian in charge. Arrival and departure of any horse must be recorded. Every horse should have its temperature taken twice daily and be physically inspected for disease daily. All horses admitted must have a current health certificate and should be vaccinated at the recommendation of the veterinarian in charge. To exit, a horse must have a health certificate endorsed 'free of EHV-1' signed by the veterinarian in charge and with vaccination requirements specified by the receiving venue. Of particular note, the PCR test does not provide a diagnosis in the absence of clinical disease and should not be used as a screening tool in clinically normal nonexposed animals.

Methicillin-Resistant *Staphylococcus aureus*

Staphylococcus aureus is a common bacterium that colonizes the skin and is associated with disease in many species. MRSA is one of the most important nosocomial pathogens and is associated with increased morbidity, mortality, duration of hospitalization, and treatment costs in humans. MRSA is an important emerging pathogen of the horse. MRSA is typically resistant to all β-lactam antibiotics (penicillin and cephalosporin families) and to many other antibiotics. *Staphylococcusx intermedius*, another coagulase-positive *Staphylococcus* spp., occurs in horses and can be methicillin resistant. MRSA in horses is associated with wound and surgical site infections, cellulitis, catheter site infections, pneumonia, septic arthritis, skin infections, endometritis, and peritonitis.

Humans can transmit MRSA to horses. Approximately 25% healthy children and adults can carry the organism in their nose or on the skin. Bacterial carriage causes no ill effects. However, a wound or an illness requiring hospitalization can result in an active infection. Approximately 0–5% horses carry MRSA in their nasal passages with a far lower percentage on the skin or in the intestinal tract. Carrier rates of up to 50% were found on some farms with a history of MRSA in horses. Carrier horses can transmit MRSA to other horses and may develop active infections under certain conditions. Carrier horses can transmit MRSA to humans. There is an equine-adapted strain that is uncommon in humans unless they have contact with horses. Studies of equine veterinarians have reported colonization rates of 10–14% with the equine strain of the bacterium.

Eighty percent of horses with MRSA infections survived in a multicenter study. Specific complication included prolonged hospital stays and additional surgeries, particularly if pneumonia or wound infections supervened. Adequate antibiotic options (topical and systemic) exist in most cases and culture and sensitivity will guide selection. The antimicrobial resistance pattern from many studies shows that MRSA isolates are frequently resistant to gentamicin, tetracycline, and trimethoprim-sulfa. Early detection of the pathogen and treatment are crucial to the outcome. Drugs, such as vancomycin, used in stubborn human multiple-drug-resistant pathogens, such as MRSA cases, should be avoided in horses and other animals.

Control of Methicillin-Resistant *Staphylococcus aureus*

Control involves implementation of all the elements of the aforementioned biosecurity measures. Ideally, horses infected or colonized with MRSA should be isolated. This may be difficult to achieve on farms. However, prevention of nose-to-nose contact and transmission by people and to people is of paramount importance. Hand hygiene is crucial even after wearing disposable gloves to touch a horse. Tissues can be quickly contaminated. Bleach solution (1:10) or quaternary ammonium compounds can be used to decontaminate the treatment area or stall. Stringent cleaning protocols must be effected for common equipment items, such as an ultrasound unit and treatment carts. MRSA organisms survive well in dust.

Standard operating procedures should be adopted for wounds, for example, at this teaching hospital, all surgical wound infections must have a sample obtained for culture and sensitivity before specific therapy is started. Furthermore, a patient who has received previous antibiotic therapy for a wound or infection that remains unresolved must have a sample obtained for culture and sensitivity at the initial examination.

Strangles in Horses

This is not an emerging disease of horses, although it remains an important infectious disease for susceptible individuals or populations. The causative agent is *S. equi* subspecies *equi*, (Lancefield Group C, Gram positive β-hemolytic bacterium). There is a close genetic relationship between *Streptococcus equi* subspecies *equi* and *Streptococcus zooepidemicus*, the former being a clone of the more genetically diverse *S. zooepidemicus* and isolates of these two organisms show at least 92% homology. Immunity is species specific; immunization with *S. zooepidemicus* does not protect against challenge by *S. equi equi*. *Streptococcus equi* (as subsequently described) is not a normal inhabitant of the equine upper respiratory tract. PCR may aid in confirming *S. equi* isolates but not active infection.

Epidemiology

Infection occurs primarily in horses 1–5 years of age and in geriatric and immune-compromised horses. In susceptible populations, morbidity is high (up to 100%) and mortality low (10%) with appropriate treatment.

Approximately 75% horses are immune for 5 years or longer if infected and not treated. Immunity is not lifelong. Most animals recover from the disease and eliminate *S. equi* over a 4–6-week period. Up to 10% affected animals continue to shed *S. equi* intermittently for prolonged periods after resolution of clinical signs.

The organism is transmitted by direct contact with nasal secretions or lymph node discharges from infected horses or by exposure to fomites. Highly concentrated or transient populations are at greater risk of contracting the disease. A strangles outbreak suggests a recent addition to a stable (premise) and a recovering horse may shed *S. equi* for several weeks. In a closed herd there is most likely to be exposure to an asymptomatic chronic carrier of the organism in the guttural pouch and paranasal sinuses. The organism survives for long periods in the environment depending on temperature and substrate.

Pathogenesis

Streptococcus zooepidemicus usually infects young horses through the nose or the mouth and colonizes the mucosal surface and tonsillar tissues of the nasopharynx. By contrast, *S. equi* is a poor colonizer. Rather than colonizing the epithelial surface, *S. equi* quickly invades tonsillar tissues of the oro- and nasopharynx and multiplies rapidly producing many extracellular microcolonies. Virulence factors contribute to pathogenicity. At the onset of fever, tonsillar tissues and one or more mandibular and retropharyngeal lymph nodes are heavily infiltrated by neutrophils and long chains of extracellular *S. equi* organisms. Mutant *S. equi* lacking virulence factors are not seen in draining lymph nodes.

Clinical Signs

The incubation period is 2–6 days, typically with fever (>103 F), lethargy, depression, and serous nasal discharge that becomes mucopurulent. Submandibular and retropharyngeal lymph nodes initially firm become fluctuant and rupture after 7–10 days (retropharyngeal lymph node abscesses may rupture internally into a guttural pouch).

Lymphadenopathy, if severe, may lead to dysphagia and respiratory distress, hence the term 'strangles.'

Pus in the guttural pouches may become inspissated, leading to chondroid formation enabling *S. equi* to persist for up to several years and be transmitted to naïve horses. There is a soft moist cough occasionally. The average course of the disease is 3 weeks. Atypical infection is associated with mild signs and minimal lymph node abscess development.

Pyrexia is the consequence of the acute phase inappropriate immune response generated by *S. equi* and can be monitored and detected in the absence of bacterial shedding. Once a strangles outbreak is confirmed, presumptively infected pyrexic horses may be identified and isolated before the organism is passed on to in contacts.

Diagnosis

Strangles diagnosis is based on clinical signs and identification (culture) or detection (PCR) of *S. equi* from a lymph node, nasopharyngeal swab, or lavage fluid from a guttural pouch. Chronic asymptomatic carriers pose the greatest difficulty in identification. Culture of lavage samples collected endoscopically is considered the gold standard for carrier detection. Serology is becoming widely used. The enzyme-linked immunosorbent assay (ELISA) for SeM protein is useful to detect recent but not current infection, assess the need for vaccination, identify horses predisposed to purpura hemorrhagica (PH), and to diagnose *S. equi*-associated PH and metastatic abscessation.

Treatment

Treatment is contentious and is a function of the stage of the disease. Penicillin is the drug of choice, although the organism is sensitive to many antimicrobials. Treatment plans have been developed, for example, (1) Horse exposed: penicillin helps to prevent seeding of the pharyngeal lymph nodes. It should be

continued for as long as the horse is exposed to the organism. Once stopped, there is a risk of the horse developing strangles. (2) Horse exhibiting signs without abscessation: penicillin may arrest disease progression. The horse should be isolated. (3) Horse exhibiting signs of lymph node abscessation: penicillin slows progression of lymph node abscessation; thus, the abscess should be hot packed, lanced, and flushed. The horse should be treated in isolation, and (4) horse systemically ill or developed complications: supportive care and penicillin should be provided.

Complications

The major complications are:

1. 'Bastard strangles,' in which metastatic (internal) abscesses occur in the mesentery or parenchymatous organs and even in the brain promulgated by inadequate antimicrobial therapy, although abscesses can occur naturally at those sites following infection. Clinical signs include intermittent colic, periodic pyrexia, anorexia, depression, weight loss, and neurological dysfunction.
2. PH – an aseptic vasculitis following reexposure to *S. equi* by natural infection or vaccination. Affected animals have higher IgA titers to SeM and to nonspecific proteins in the *S. equi* culture supernatant and immune complexes of IgA and M-like proteins. There is an association with the attenuated live intranasal *S. equi* vaccine. Clinical signs include a mild transient reaction to a severe and fatal form, with pitting edema of limbs, trunk, and head; petechiation and ecchymoses of mucosae; and colic. Vasculitis may lead to skin sloughing and infarcts of skeletal muscle. Death can result from pneumonia, cardiac arrhythmias, renal failure, or gastrointestinal disorders.

Other complications of strangles include guttural pouch empyemia and chondroid formation; septicemia, development of infectious arthritis, pneumonia, and encephalitis; retropharyngeal abscesses; laryngeal hemiplegia; tracheal compression following abscesses in the cranial mediastinal lymph nodes; endocarditis or myocarditis following abscess formation; suppurative necrotic bronchopneumonia; and two types of myopathies (myositis) – one a vasculitis with infarction of skeletal muscle and pulmonary and gastrointestinal tissues characterized by unrelenting pain; the second affecting quarter horses showing malaise, significant muscle atrophy, and chronic active rhabdomyolysis.

Control During an Outbreak

Control follows the detailed biosecurity measures that are integral to the sensible management of an infectious disease. Specifically, prevent the spread of infection to horses on other premises and to new arrivals. Ideally, all movement of horses on and off the premises must be stopped and new horses should be isolated for 3 weeks. Identify symptomatic and asymptomatic carriers by sampling nasopharyngeal or guttural pouch regions at weekly intervals and test for *S. equi* by culture and PCR. Infectious horses should be isolated from those screened negative for *S. equi*. Rectal temperature should be taken twice daily. The isolation area should be cordoned off and staff should be dedicated to this area with protective clothing and footwear. The area and contents should be disinfected. After clinical signs disappear, perform at least three consecutive nasopharyngeal swabs or lavage for *S. equi* at approximately weekly intervals and test by culture and PCR to detect carriers.

Prevention

Less immunity is provided following vaccination than that following recovery from natural disease.

The intramuscular killed (*S. equi* extract) vaccine with an adjuvant is used more widely than the intranasal attenuated *S. equi* live culture, which should not be administered with parenteral injections or at the time of invasive procedures. No current vaccine guarantees prevention of strangles in vaccinated horses.

Vaccination of infected animals during an outbreak may be associated with PH, and vaccination during an outbreak is controversial.

The 2005 American College of Veterinary Internal Medicine Consensus Statement recommends measuring SeM-specific antibody titers by ELISA before vaccination and to not vaccinate if titers $\geq$1:3200. Horses previously given the intranasal vaccine, nonthoroughbreds and nonwarmbloods, are significantly more likely to have higher titers ($>$1:1600).

Generation of an immune response to multiple protective epitopes may be required to achieve the greatest protection. Development of a strangles vaccine (ideally with differential diagnostic potential) benefitting from an improved immunogenicity and safety profile is a priority to achieve widespread protection against strangles.

Introduction

The ultimate grand challenge of our times is nothing less than the sustainability of the Biosphere and our place in it. Can we learn how to meet our needs today without compromising the ability of future generations to meet theirs? With the 7 billionth member of humanity having joined the planet, achieving global food security sustainably is the single most important issue facing civilization and, by implication, the planet in the next 30 years. Over the coming decades, food and agricultural production systems must be significantly enhanced to respond to a number of transformative changes, such as a growing world population; increasing international competition; globalization; shifts to increased meat consumption in developing countries; and diet-related disease and rising consumer demands for improved food quality, safety, health enhancement, and convenience. New and innovative techniques will be required to ensure an ample supply of healthy food by improving the efficiency of the global agriculture sector. To confound this situation the inequity between the affluent and the developing countries will continue to grow and only a handful of technologies are sufficiently scale neutral to help with redressing this imbalance. Of even greater concern is the very immediate need of global food security. In 2012, the United Nations issued an unprecedented warning about the state of global food supplies. They noted that global food reserves have reached their lowest level in almost 40 years and that failing harvests in the United States, Ukraine, and other countries in 2012 have eroded reserves to their lowest level since 1974 when the global population was much lower. They warned that world grain reserves are so dangerously low that another year of severe weather in the United States or other food-exporting countries could trigger a major hunger crisis by 2013. Clearly, unprecedented needs require effective solutions (Eliasson, 2012).

Over the millennia many technologies have been developed and used to enhance productivity of the original coterie of cultivated crops and to bring more into the domestic fold. In the latter half of the twentieth century, major improvements in agricultural productivity were largely based on selective breeding programs for plants and animals, intensive use of chemical fertilizers, pesticides and herbicides, advanced equipment developments, and widespread irrigation programs. This has been a very successful model for raising productivity; yet, these improvements have brought the corresponding problems of an increasing narrow genetic base of crop plants and domestic animals, pests resistant against chemical pesticides, adverse impacts on environmental quality, and capital-intensive production. In addition, from a global perspective, these advances have been the prerogative of more affluent regions. Farmers in developing countries have not had access to many of these technologies and capital-intensive methods of production. During the coming decades, food and agricultural production systems must be significantly enhanced to respond to a number of wide-ranging and far-reaching transformations, including a changing climate, growing world population, increasing international competition, globalization, shifts to increased meat consumption in developing countries, and rising consumer demands for improved food quality, safety, health enhancement, and convenience. New and innovative techniques will be required to ensure an ample supply of healthy food against competing interests and this can only be achieved by improving the effectiveness of all components of the global agriculture sector. Innovation is essential for sustaining and enhancing agricultural productivity and this involves new, science-based products and processes that contribute reliable methods for improving quality, productivity, and environmental sustainability.

At its most basic level food is the source of nutrition to meet daily requirements but is now taking on an ever greater role in the quest for health optimization. The latter focus is a luxury that is primarily the purview of an affluent society and has little relevance in many areas where mere survival is the driving force. From the basic nutrition perspective, there is a clear dichotomy in demonstrated need between different regions and socioeconomic groups, the starkest being addressing injudicious consumption in the developed world and undernourishment in less developed countries (LDCs). Both extremes suffer from forms of malnourishment: one through inadequate supply and the other, in many but not all instances, through inappropriate choices; the latter often influenced by economic considerations. From the food deserts of inner cities to the real barren wastelands of many regions, access to a healthy diet is a challenge. Dramatic increases in the occurrence of obesity, cardiovascular disease, diabetes, cancer, and related ailments in developed countries are in sharp contrast to chronic undernutrition and genuine malnutrition in many LDCs. Both problems require a modified food supply, and the tools of biotechnology, although not the sole solution, do have a significant part to play.

Worldwide plant-based products comprise the vast majority of human food intake, irrespective of location or financial status (Mathers, 2006). In some cultures, either by design or default, plant-based nutrition comprises almost 100% of the diet. Given this one can deduce that significant nutritional improvement can be achieved via modifications of staple crops. New and innovative techniques will be required to improve the efficiency of the global agriculture sector to ensure an ample supply of high quality food. To confound this situation the inequity between the affluent and developing countries will continue to grow and only a handful of

technologies are sufficiently scale-neutral to help with redressing this imbalance. In October 2009, the United Nations' Food and Agriculture Organization (FAO) determined that farming in developing countries needs US$83 billion of annual investment for production to feed the world in 2050. The 2008 World Bank Development Report emphasized, "Agriculture is a vital development tool for achieving the Millennium Development Goals that calls for halving by 2015 the share of people suffering from extreme poverty and hunger" (World Bank, 2008). The Report notes that three out of every four people in developing countries live in rural areas and most of them depend directly or indirectly on agriculture for their livelihoods. It recognizes that overcoming abject poverty cannot be achieved in sub-Saharan Africa (SSA) without a revolution in agricultural productivity for resource-poor farmers in Africa, many of whom are women. Likewise the FAO publication, the State of Food Insecurity in the World 2011, highlights the differential impacts that the world food crisis of 2006–08 had on different countries, with the poorest being most affected. Although some large countries were able to deal with the worst of the crisis, people in many small import-dependent countries experienced large price increases that, even when only temporary, can have permanent effects on their future earnings capacity and ability to escape poverty. African smallholder farmers are some of the most impoverished people in the world (43% are women) and they account for 80% of food production in SSA. Some people argue that their future will be driven by the private sector – the UK's Department for International Development has been working to link up businesses with smallholder farmers. Giant food retailers are also starting to realize that they need to look after African smallholders to safeguard their future. Although not the only answer, the technological advances of biotechnology can help to assist with providing food sufficiency and economic independence for such resource-poor regions.

Most of the innovative technologies that have been applied to production agriculture have come into common usage without much controversy or even knowledge by the average consumer. If asked, the majority of respondents would no doubt agree that this involves at some level new, science-based products and processes that contribute reliable methods for improving quality, productivity, and environmental sustainability. In the past we have not regulated changes in agriculture based on unpredictable socioeconomic consequences. However, some recent innovative technologies, namely biotechnology and more specifically recombinant deoxyribonucleic acid (DNA) technology, have inspired debate in a manner unlike any other previous technological development. Although biotechnology has introduced a new dimension to such innovation, offering efficient and cost-effective means to produce a diverse array of novel, value-added products and tools is not viewed with unmitigated optimism by all existing and potential stakeholders. The stakeholders involved in this debate are many and diverse, ranging from academic and industrial scientists to conventional and organic producers, to international, national, federal, state, and local government and nongovernmental organizations (NGOs) and agencies, to activist groups and, of course, consumers. How this technology is viewed depends very much on the perspective from which it is viewed and the goals and objectives of the different players involved. And this perspective is formed by the complexity of the prism through which it is viewed. Each individual's prism is built of our cumulative life experiences, educational background, innate prejudices, world view, and, of course, personal objectives. To most producers, and academic and industrial researchers, biotechnology is seen as offering a new dimension to innovation, providing efficient and cost-effective means to produce a diverse array of value-added products and tools. To some of our national and international markets it is seen as a trading barrier or chip, depending on which side of the fence one is standing. To others it represents an unnecessary, and for some, unnatural risk at a broad level to our food system and environment and at a very fundamental level to a way of life or code of beliefs. Unfortunately, as in every walk of life, there are some who seize on these many nuances of perception, and indeed fear, to propagate their own, covert or otherwise, agenda. Although on the surface scientific facts may appear immutable, how those facts are presented within a socioeconomic context makes for an interesting study of the stratagems used by the diverse stakeholders to advance their own agenda for any given target demographic. These tactics are played out on local and world stages and often by the same players who customize their approach depending on the context.

The vast majority of biotechnology products approved to date are in the area of agronomic traits most specifically to protect against biotic stress. The principal focus in the immediate future will remain on agronomic traits, especially the area of pest control but with an increasing interest in abiotic stress tolerance, which is gaining prominence as external pressures from climate change to land use is challenging productivity. In 2013, 175.2 million hectares of biotech crops were grown globally, at an annual growth rate of 3%, up 5 million from 170 million hectares in 2012. Of the 18 million farmers who grew biotechnology crops in 2013, more than 16.5 million (90%) were in developing countries, which produced more global biotechnology crops than industrial countries (52% vs. 48%), and considerable more emerging economies (19% vs. 8%) grew these crops (James, 2014). More than 7.5 million small farmers in China and another 7.3 million small farmers in India collectively planted a record 14.5 million hectares of biotechnology crops (**Figure 1**; James, 2014). In 2013, Bangladesh approved their first genetically modified (GM) crop Bt eggplant. The Sudan became the fourth country in Africa, after South Africa, Burkina Faso, and Egypt, to commercialize a biotechnology crop – Bt cotton – in 2012. Iran and Cuba also planted GM crops, but it is challenging to document numbers for these countries. In 2010, Pakistan planted Bt cotton, as did Myanmar, and notably Sweden, the first Scandinavian country to plant a biotechnology crop, planted 'Amflora,' a potato with high amylose starch for industrial applications. Germany briefly resumed adoption of biotechnology crops by planting Amflora in 2010. However, both ceased after Amflora was pulled from the market in 2012. BASF cited opposition to the technology as their reason for withdrawing the potato. Currently, only one GMO crop is grown commercially in Europe – an insect-resistant variety of maize developed by Monsanto. It is sown on approximately 100 000 ha (247 000 acres) of farmland, mainly in Spain.

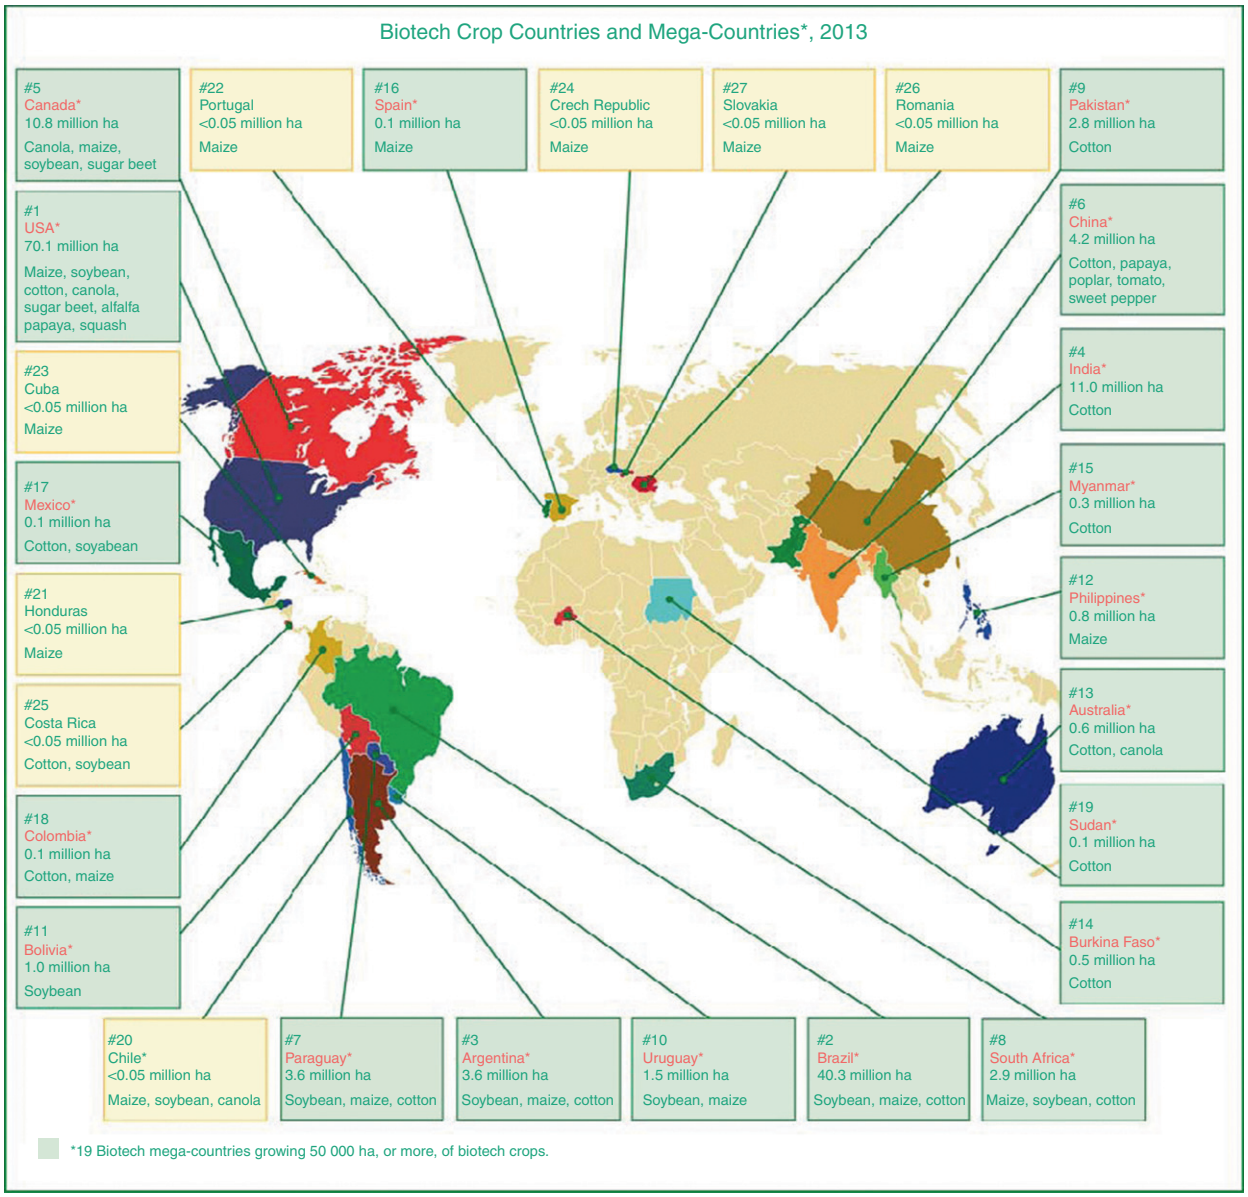

Figure 1 Adapted from James, C., 2013. Global Status of Commercialized Biotech/GM Crops: 2012. ISAAA Brief No.44. Ithaca, NY: International Service for the Acquisition of Agri-biotech Applications. Available at: http://www.isaaa.org/ (accessed 24.02.13).

Agronomic Traits and Sustainability

Agricultural biotechnology already has helped farmers around the world boost their productivity and grow crops in more ecologically healthy fields while allowing much more efficient use of resources. This technology allows reduced tillage, which cuts down on greenhouse gas emissions, water runoff, soil erosion, and fuel consumption. Improved pest control increases yields on existing acreage and reduces the pressure to convert forests and wildlands into farmland. Research by Brookes and Barfoot shows that, in the first 15 years of GM crop cultivation, pesticide use (which includes both insecticides and herbicides) fell by more than 448 million kg worldwide, or a decline of 9% (see Section 'Relevant Websites'). In addition to the obvious direct benefits, less spraying means fewer tractor passes, contributing to lower carbon dioxide emissions. The technology has reduced pesticide spraying by 443 million kg (approximately 9.1%) and, as a result, decreased the environmental impact associated with herbicide and insecticide use on these crops, as measured by the indicator the Environmental Impact Quotient, by 17.9%. In addition, insect-resistant maize has a collateral effect – less insect damage results in much less infection by fungal spores, which reduces mycotoxins that are known health risks resulting in diseases such as liver cancer in humans and animals. Bt corn resulted in a 90% reduction in mycotoxin fungal fumonisins. In addition to the obvious health benefits, the total US economic benefit is estimated to be approximately

US$23 million annually (Wu, 2006). The only 'natural' way to control those fungi is the use of copper sulfate, which has one of the highest toxic hazard ratings of acceptable pesticides and selects for antibiotic-resistant bacteria in the soil (Berg *et al.*, 2005).

Meanwhile, the economic benefits experienced by large- and small-scale farmers in both industrialized nations and lesser developed countries have been significant. The Brookes and Barfoot (2014) analysis shows that there have been very significant net economic benefits at the farm level amounting to US$116.9 billion during the 17-year period, 1996–2012, of which 58% were due to reduced production costs (less plowing, fewer pesticide sprays, and less labor) and 42% due to substantial yield gains of 377 million tonnes. The corresponding figure for 2012 alone was 83% of the total US$18.7 billion gain due to increased yield (equivalent to 47 million tonnes) and 17% due to lower cost of production (Brookes and Barfoot, 2014). The majority (51.2%) of these gains went to farmers in developing countries. GM technology has also made important contributions to increasing global production levels of the four main crops, having added 110 million tonnes and 195 million tonnes, respectively, to the global production of soybeans and maize since the introduction of the technology in the mid-1990s. In addition, the environmental footprint associated with pesticide use was reduced by 18.5%, and there was a reduction in carbon dioxide emissions in 2012 alone by 26.7 billion kg, equivalent to taking 11.8 million cars off the road for 1 year (Brookes and Barfoot, 2014).

Phelan in 2007 argued that there are two major threats to food production: farm subsidies for biodiversity-friendly farmingand expansion of protected areas to protect biodiversity (approximately 15% of arable land). He maintains that neither work is intended and both can damage biodiversity. But, in each case, there is much at stake for vested interest groups. Coming from what arguably may be considered an alternative perspective, a 2005 paper from the Royal Society suggested that intensive high-yield farming on less land is better for wildlife than 'wildlife friendly' less-efficient farming (Green *et al.*, 2005). They provide convincing evidence that without yield increase land use will double by 2050 and that this effect will be especially significant in developing countries, such as China and India, where without greater productivity four times the land area will be needed to support their expanding populations. They show that in Latin America where increased productivity was achieved there was a significant decrease in deforestation; those producers with greatest yield increase had lower land use. This proposition was supported by the demonstration of biotechnology's contribution to conserving biodiversity by saving 108.7 million hectares of land from being converted to agricultural production (James, 2013).

An earlier study by researchers at Denmark's National Environmental Research Institute (NERI) monitored fields of conventional and glyphosate-tolerant sugar beet. They found that the GM plots supported more plant species and insects than the conventional plots, thus providing more food for birds, and other types of wildlife use of transgenic crops increased biodiversity compared with traditional herbicide treatments (Elmegaard, 2001). Proper measurements in the United Kingdom indicate that no-till, (directly compared with plowed organic fields on the same farm and using the same farmer) uses only one-third fossil fuel, uses land much more efficiently, reduces nitrate (and pesticide) runoff by at least half, and increases soil carbon that is lost when plowed. In addition, bird territories are orders of magnitude greater, soil erosion almost vanishes, and soil invertebrates such as earthworms soar in numbers, as do predatory arthropods to keep pests down. Organic fields in the United Kingdom see a threefold rise in weeds on conversion that necessitates use of the plow (Trewavas, 2008).

Therefore, reduced-till agriculture means healthier soil, with reduced erosion and far less carbon dioxide release. Soil carbon sequestration will be an important part of any international strategy to mitigate the increase in atmospheric CO_2 concentrations. By adopting more sustainable management practices, agriculture may play a large part in enhancing soil carbon sequestration across the globe. One way is by reducing the amount of conventional tillage; after long-term tillage soil carbon stocks are depleted. Through reduced-till production, this technology allowed significant reduction in the release of CO_2 emissions in 2011 alone of 23.1 billion kg, which is equivalent to taking 10.2 million cars off the road (Brookes and Barfoot, 2012). In general, cultivation is not a sustainable practice. It is energy intensive, exposes soil to wind and water erosion. It allows rain to compact the soil and increases the oxygen content, thus allowing organic matter to oxidize away. In turn, lower organic matter in the soil allows more compaction and more nutrient loss. Additionally, in warmer and drier climates evaporative water loss may be reduced as residue remains on the soil surface creating a wetter and cooler soil microclimate.

Although North America remains the epicenter for cutting-edge GM research, other regions, namely China, are emerging as contenders on the global stage. Agricultural science is now China's fastest-growing research field with China's share of global publications in agricultural science growing from 1.5% to 5% in 1999 and 2008 respectively (James, 2011). China's early experience with Bt cotton demonstrated the direct and indirect benefits of its investment in plant biotechnology research and product development. In 2002, Bt cotton was grown in 2.1 million hectares by around 5 million farmers. At that time the average Bt cotton farmer had reduced pesticide sprayings for the Asian bollworm from 20 to 6 times per year, applications were reduced by 59–80% compared with conventional cotton (assessed in 3 years of use) and produced a kilogram of cotton for 28% less cost than the farmer using non-Bt varieties. Net revenues increased by US$357–549 ha^{-1} compared with conventional cotton (assessed in 3 years of use). Ultimately, however, it is the social benefits from reducing exposure to insecticides and saving lives that is the real payoff.

The demand for productivity-enhancing technologies by farmers and for cost savings by consumers, the rate of increase in research investments, and success with Bt cotton suggest that products from China's research program will one day become widespread inside China. Indeed, China is emerging as one of the trend setters in the adoption of novel traits as more recently it is setting the pace for new approvals with Bt rice and phytase maize approved on 27 November 2009. Rice

is the principal staple for much of the world and maize is the largest animal feed source. Bt rice has the potential to increase yields up to 8%, decrease pesticide use by 80% (17 kg ha^{-1}), and generate US$4 billion in benefits annually (James, 2011). The phytase approval is a major step forward in approvals as it is the first transgenic since the FLAVR SAVR tomato focusing on a 'quality' trait. However, it is far more than this, both literally and figuratively, as this single trait addresses several issues from nutritional to environmental ones as expanded on later. Two further 'quality' traits are under consideration for deregulation: the Arctic apple, which has been modified to resist oxidation when the apple is cut and the injured cells are exposed to oxygen activating the polyphenol oxidase (PPO) gene. To achieve this effect Okangan have co-expressed PPO genes and have effectively achieved reduced oxidation by silencing the endogenous PPO gene (Carter, 2012). The second is JR Simplot's reduced acrylamide potato, described below.

The first GM crop to be released for commercial cultivation in India was Bt cotton, developed by the Maharashtra Seed Company (Mahyco) in partnership with Monsanto. The approval, which was given in 2002, came after several years of field trials following the biosafety procedures laid down by the government. Three cotton hybrids were granted permission for field sowing in six states for 3 years. For the first season, farmer demand for Bt cotton seed was very high; it is estimated that 44 500 ha of certified Bt cotton were planted by nearly 55 000 farmers (Choudhary and Gaur, 2008). However, the initial events thrived in regions that resembled the area in which they were originally developed but did not perform very well in growing regions with disparate climate challenges. It was not until the trait was introgressed into locally adapted varieties that Bt cotton thrived in all growing regions. Between 2005 and 2006 the biggest impact of this approach was realized. From 3 Bt cotton hybrids in 2002 to 62 in 2006, the rapid deployment of Bt cotton hybrids based on different agroclimatic conditions resulted in decreased insecticide sprays by 39% and increased yields 31%, resulting in increased profit per hectare of 88% or US$250. Over this period of rapid deployment, the average cotton yields increased from 308 kg ha^{-1} to 450 kg ha^{-1} of lint (of this increase, 50% could be attributed to Bt technology). Over this period raw cotton exports also rose from 0.9 million bales in 2005 to 4.7 million by 2006 and 5.9 by 2007. By 2009, 5.6 million resource-poor farmers in India planted 8.4 million hectares of Bt cotton, equivalent to 87% of the 9.6 million hectare national cotton crop. The increase from 50 000 ha when Bt cotton was first commercialized in 2002 to 8.4 million hectares in 2009 represents an unprecedented 168-fold increase in 8 years (Choudhary and Gaur, 2010). Between 2002 and 2008, Bt cotton generated economic benefits valued at US$5.1 billion for farmers, halved insecticide requirements, contributed to the doubling of yield, and transformed India from a cotton importer to a major exporter. Choudhary and Gaur (2010) contended that the deployment of Bt cotton over the years has resulted in India becoming the number one exporter of cotton globally as well as the second largest cotton producer in the world.

However, despite the success of Bt cotton, the expected successful commercialization of Bt eggplant never materialized as an effective opposition managed to scupper its approval. Bt eggplant, or brinjal as it is referred to in India, was found to be effective against fruit and shoot borer (FSB), with 98% insect mortality in shoots and 100% in fruits compared with less than 30% mortality in non-Bt counterparts. The multilocation research trials confirmed that Bt brinjal required, on average, 77% less insecticides than non-Bt counterparts for control of FSB and 42% less for the control of all insect pests of brinjal. The benefits of Bt brinjal translate to an average increase of 116% in marketable fruits over conventional hybrids and 166% increase over popular open-pollinated varieties. Furthermore, the significant decrease in insecticide usage reduced the farmers' exposure to insecticides and results in a substantial decline in pesticide residues on brinjal fruits (Bricknel, 2010). Scientists have estimated that Bt brinjal will deliver farmers a net economic benefit ranging from US$330–397 per acre with national benefits to India exceeding US$400 million per year. However, in February 2010 the environmental minister announced a 6-month moratorium citing, "There is no overriding food security argument for Bt brinjal. Our objective is to restore public confidence and trust in Bt brinjal," clearly articulating the fact that the decision was not based on scientific analysis or risk assessment.

A number of other multi-institutional projects have also been launched in India, including the development of transgenics for resistance to geminiviruses in cotton, mungbean, and tomato; resistance to rice tungro disease; development of a nutritionally enhanced potato with a balanced amino acid composition; and development of molecular methods for heterosis breeding. Other transgenic crops that are awaiting approval for commercial cultivation include transgenic herbicide-tolerant mustard hybrids and nutritionally enhanced potato varieties. However, despite the resounding success of Bt cotton, given the experience with Bt brinjal, it is difficult to be optimistic about the prospects for commercialization of food crops. To reinforce this notion in 2012 an interim report of the technical expert committee (TEC) appointed by the Supreme Court of India recommended a ban on open field trials, including any ongoing trials, for 10 years, which will result in a serious impact on the application of biotechnology to Indian agriculture. However, in October 2012 the Supreme Court decided that before considering this interim recommendation they would seek the views of all stakeholders, including the agriculture ministry and the GM crop industry, on the issue (Times of India, 2012).

A similar context applies to another potentially valuable disease resistance system. Late potato blight is one of the most devastating plant diseases. It is caused by the oomycete *Phytophtera infestans*, a pathogen of the potato and, to a lesser degree, the tomato. No potato has been bred to date that has any measure of resistance to the pathogen. Approximately 15–20% of annual global crop yields of approximately 330 million tonnes fall victim to the disease (and up to 75% in many LDCs) that was introduced to Europe in the mid-nineteenth century and was responsible for the Irish potato famine. The International Potato Center (Lima, Peru) estimates the annual value of these losses to be US$3–5 billion, excluding losses from tomato infestations. In the potato, *Solanum tuberosum*, there are four main dominant genes for resistance to blight infection, *R1* through *R4*. An additional 7 genes were identified, 5 of which are alleles of the complex *R3* locus (for a total of 11 dominant *R* genes). Hybridization with wild Mexican

species began in 1909 and continues to the present. However, in spite of constant effort, *P. infestans* strains have rapidly developed that overcome genetic disease resistance. Chemical fungicides have been developed to control blight but these also succumb to the versatility of the organism. The only acceptable organic control system is copper sulfate, which has a hazard rating of one and is neither desirable nor sustainable as a chemical control system.

The oomycete has two mating types (A1 and A2), both of which appeared first in Mexico; however, only the A1 mating type was present in European potatoes until 1978 when the A2 mating type appeared in Britain and Ireland. The presence of the two mating types greatly enhances gene exchange, leading to accelerated loss of genetic resistance and fungicide control. Potato has a narrow breeding base, is highly heterozygous, and suffers from acute inbreeding depression, making introduction of resistant traits to market-adapted genotypes difficult. Attempts to introduce various resistance genes from wild *Solanum* species have been undertaken in the past century, but *P. infestans* has evolved much faster, enabling it to counteract these breeding efforts. Early resistant potatoes were obtained using true sexual hybridization with wild Mexican species, but these resistant hybrids soon succumbed to mutant strains of the blight. A wild Mexican plant, *Solanum bulbocastanum*, is stably resistant to blight but could not be sexually crossed with potatoes. Transgenic breeding lines have many advantages over other methods to introduce resistance, especially speed and robust resistance. The blight pathogen suppresses the potato defense genes in susceptible plants but is thwarted by successful defense genes in resistance plants. The NBS-LRR (nucleotide-binding site leucine-rich repeat) resistance genes in plants are predominantly localized in the cell cytoplasm, although many move to the nucleus after infection and do not span the cell membrane but are activated by pathogen signals that penetrate the cell. The German company BASF transformed the potato using two plasmids, each containing copies of the wild Mexican *S. bulbocastanum* NBS-LRR resistance genes *Rpiblb1* and *Rpi-blb2*. They confer robust resistance and are a much preferred and more sustainable system than the use of topical fungicides, natural or otherwise. In October 2011 the company requested cultivation and marketing approval as a feed and food from the EU Food Safety Authority (EFSA) for their GM 'Fortuna' potato with a notion of commercializing it by 2015 (BASF, 2011). However, in March 2012 BASF announced the discontinuation of its breeding efforts for all GM crops adapted to European conditions (Dixelius, 2012). It will close its agricultural branch in Europe and is choosing instead to focus on the American and Asian markets.

The vast majority of products approved to date are in the area of agronomic traits, most specifically biotic stress. The principal focus in the immediate future will remain on agronomic traits, especially the area of pest control, but with an increasing interest in abiotic stress tolerance, which is gaining prominence as external pressures from climate change to land use change. On the biotic stress tolerance side the focus is expanding to multitiered control systems. This in theory serves a double advantage, primarily expanding the effectiveness of the broad-based resistance events but also allowing more effective management of the resistance trait as there is less selective pressure when genes are stacked. SmartStax, an eight-trait event developed through collaboration between Monsanto and Dow, takes advantage of multiple modes of insect protection and herbicide tolerance against above- and below-ground insects and provides broad herbicide tolerance, including Yieldgard VT Triple (Monsanto), Herculex Xtra (Dow), RoundUp Ready 2 (Monsanto), and Liberty Link (Dow). It is currently available for corn, but cotton, soybean, and specialty crop variations are in the pipeline. It is estimated that this should require only 5% refuge acres as opposed to the 20% required of older technologies to militate against pest tolerance (Choudhary and Gaur, 2010).

On the second area of agronomic traits, namely abiotic stress, there is a meta issue that overlays much of the individual efforts, that is, climate change. This poses a real challenge in terms of available agricultural land and fresh water use. Apart from the obvious effects of climate change, the decline of crop yields, ocean acidification, poor plant nutrition and abiotic stress, population displacement, and threatened ecosystems are effects underlined by the Stern Report (2006) as potential consequences of climate change. In addition, there are also broader, more systemic effects of drought beyond food insecurity, such as decreased household income, the loss of assets due to slaughter of livestock, health threats due to the lack of water for hygiene and household uses, environmental degradation, and less sustainable land management. These effects must be considered in the light of growing population levels. In order to feed the overall population, the world will have to double its rate of agricultural production over the next 25 years, despite having already quadrupled it in the last 50 years. It is estimated that merely 10% of world's arable land may be categorized as free from stress. The rapid change in environmental conditions is likely to override the adaptive potential of plants. Such abnormal environmental parameters include drought, salinity, cold, freezing, high temperature, waterlogging, high light intensity, ultraviolet (UV) radiation, nutrient imbalances, metal toxicities, and nutrient deficiencies, which are collectively termed as abiotic stress. Severe drought accounts for half the world's food emergencies annually. In 2003, the World Food Program spent US$565 million in response to drought in SSA (Anderson, 2005). In this context, solutions must be developed to adapt crops to existing but also evolving conditions, such as deteriorating soils or harsher conditions, such as cold, heat, drought, and salinity.

The agriculture sector is both a contributor to and provider of potential solutions to this phenomenon. It impacts two of the principal components of climate change – greenhouse gases and water. Agriculture is a major source of the former emissions. Practices such as deforestation, cattle feedlots, and fertilizer used currently account for approximately 25% of greenhouse gas emissions. When broken down in total, this amounts to 14% of carbon dioxide emissions, 48% of methane, and 52% of nitrous oxide emissions (Stern, 2006). In addition, this sector uses a significant amount of available fresh water; approximately 70% of the water currently consumed by humans is used in agriculture, and this is likely to increase as temperatures rise. The impact between resource-poor LDCs and developed countries is likely to be asymmetrical with much greater impacts on resource-poor farmers.

Given the potential impacts of climate change on the range and extent of agricultural productivity and the impact of

agricultural practice itself on global warming, effective technology should play a substantial part in militating against climate change. This is especially relevant in emerging countries where producers and consumers are more subject to the mercy of the vagaries of climate fluctuations than in the west where there is greater capability of responding to the effects and managing resources. Green biotechnology offers a set of tools that can help producers to limit greenhouse gas emissions as well as adapting their agricultural techniques to shifting climates. The three major contributions of green biotechnology to the mitigation of the impact of climate change are greenhouse gas reduction, crop adaptation (environmental stress and changing niches) crop protection, and yield increase in less desirable and marginal soils.

On the first of these issues, greenhouse gas reduction in addition to carbon dioxide, agriculture contributes two of the other major greenhouse gases, indeed one of them, nitrous oxide, has a global warming potential of approximately 300 times that of carbon dioxide. In addition, nitrous oxides stay in the atmosphere for a considerable period. Nitrous oxide is produced through bacterial degradation of applied nitrogen fertilizer, which can also contribute to eutrophication at ground level, so its reduction is desirable on several levels. However, nitrogen is essential for crop production because it is quantitatively the most essential nutrient for plants and a major factor limiting crop productivity. One of the critical steps limiting the efficient use of nitrogen is the ability of plants to acquire it from applied fertilizer. Therefore, the development of crop plants that absorb and use nitrogen more efficiently can serve both the plant and the environment. Arcadia Biosciences of Davis, CA developed nitrogen-efficient crops by introducing barley AlaAT (alanine aminotransferase) into both rice and canola. In a report, Arcadia's Nitrogen Use Efficiency (NUE) technology produces plants with yields that are equivalent to conventional varieties but which require significantly less nitrogen fertilizer because the AlaAT gene allows more efficient use. Compared with controls, transgenic plants also demonstrated significant changes in key metabolites and total nitrogen content, confirming increased nitrogen uptake efficiency. This technology has the potential to reduce the amount of nitrogen fertilizer that is lost by farmers every year due to leaching into the air, soil, and waterways (Omanya *et al.*, 2008). In addition to environmental pressures, nitrogen costs can represent a significant portion of a farmer's input costs and can significantly impact farmer profitability. Farmers spend US$60 billion annually for 150 million tonnes of fertilizer (Svoboda, 2008). The technology has been licensed to DuPont for maize and to Monsanto for application in canola.

The second area where green technology can help in a changing climate is crop adaptation to environmental stress and changing niches. Under stress, plants divert energy into survival instead of producing biomass and reproduction, so addressing this impact should have substantial effect on yield. In addition, improved stress tolerance allows an expanded growing season, especially earlier planting, and further reduces yield variability and grower financial risk. The most critical of these stresses is water. One of the most effective methods of addressing water limitation problems, namely irrigation, unfortunately is also one of the major causes of arable land degradation. It is estimated that 24.7 million acres of farmland worldwide is lost each year due to salinity buildup resulting from over irrigation. In fact, salinity limits crops on 40% of the world's irrigated land (25% of the United States). To address the extreme end of irrigation impact, Sottosanto *et al.* (2007) used AtNHX1, the most abundant vacuolar Na^+/H^+ antiporter in *Arabidopsis thaliana*, which mediates the transport of Na^+ and K^+ into the vacuole. By overexpressing this vacuolar Na^+/H^+ antiporter transgenic tomatoes were able to grow, flower, and produce fruit in the presence of 200 mM sodium chloride (Sottosanto *et al.*, 2007).

It is estimated that water stress is the most important variable in determining crop yield and can explain approximately 80% variance in yields (Shin *et al.*, 2009). Even at a more moderate level of impact it is estimated that approximately 70–80 million acres in the United States suffer yield losses due to moderate water stress (Kramer, 1980). The most critical time for water stress is near pollination and flowering where yields with or without irrigation can vary by up to 100%. This effect is clearly demonstrable in dry land production where yields can be cut in half in the absence of irrigation. At this time approximately 15% of US maize acres are irrigated. Given the negative effective and cost of irrigation, it is estimated that 20 million acres in the United States would benefit from a drought tolerance gene that gives a 10% yield increase. It would also allow shifting of high-value crops into production on more marginal land.

One of the first commercialized products to have included a 'yield gene' was Monsanto's second generation Roundup Ready 2 Yield® Soybeans, which not only include the glyphosate-tolerant trait but also were developed using extensive gene mapping to identify specific DNA regions that segregate with yield increase (Monsanto, 2010). First-generation Roundup Ready varieties had demonstrated yield drag due to the unfortunate insertion close to a gene that influenced seed size and co-segregated with the transgene. The second generation is a good example of the power of combining recombinant DNA technology with genomics tools. The company claims that following 4 years of field trials across six US states showed 7–11% higher yields, compared with the first generation of Roundup Ready soybeans. However, there have been some problems with fungal (white mold) susceptibility in certain regions. At the National Technical Biosafety Committee (CTNBio) meeting in Brazil in August 2010, the committee approved the Bt-enhanced version of this product for planting in Brazil.

As noted, transcription factors are some of the most versatile tools being employed in developing stress-tolerant plants. One of the most versatile classes of transcription factors in so far as environmental response is concerned is the dehydration-responsive element-binding protein (DREB) transcription factors that are involved in the biotic stress signaling pathway and can activate as many as 12 resistant functional genes relying on DRE members of *cis* regulation under adverse conditions, for instance, *rd29*, *cor15*, and *rd17* cause proline content to rise so as to enable plants to improve in many resistances, such as drought, freezing, and salt tolerance (Agarwal, 2006). It has been possible to engineer stress tolerance in transgenic plants by manipulating the expression of DREBs. One isolated from *Arabidopsis* has improved drought tolerance, increasing productivity by at least twofold during

severe water stress. DroughtGard™ maize is the first commercially available transgenic drought-tolerant crop. Hybrid seed sold under this trademark combines a novel transgenic trait (based on the bacterial cspB gene, an ribonucleic acid (RNA) chaperone, which helps to maintain normal physiological performance under stress by binding and unfolding RNA molecules so that they can function normally) with Monsanto's optimized conventional breeding program. In field trials using this approach, maize yields have increased under water stress by up to 30%. The yield gain of this variety under drought appears to occur due to slowing of growth, specifically under drought stress such that existing soil moisture is saved for the critical period surrounding flowering, resulting in less kernel abortion, higher harvest index, and greater yield (Castiglioni *et al.*, 2008).

Other approaches include modification of individual genes involved in stress response and cell signaling. For example, drought-tolerant canola engineered to reduce the levels poly (ADP-ribose) polymerase, a key stress-related protein in many organisms, shows relative yield increases of up to +44% compared with control varieties. A subset of the transcription factors, homeodomain leucine zipper proteins (HDZip), plays a role in regulating adaptation responses, including developmental adjustment to environmental cues, such as water stress in plants (Deng *et al.*, 2006). One of these effectors is abscisic acid (ABA), an important plant regulator controlling many environmental responses, including stomata movement that is itself modulated by the DREB elements. Some work is being done on modifying HDZip directly, whereas other works aim to modify it indirectly, for example, downregulating farnesyltransferase, a signaling system in the production of ABA and stomata control, which results in stomata closure and water retention.

Eduardo Blumwald is also working on modifying basic acid to enhance the tolerance of plants to water deficit by delaying the drought-induced leaf senescence and abscission during the stress episode. Using tobacco plants expressing an IPT gene under the control of a stress- and maturation-induced promoter they showed that delayed drought-induced leaf senescence resulted in remarkable drought-tolerant phenotypes as well as minimal yield loss when plants were watered with only 30% of the water used under controlled conditions (Zhang, 2010). This is now being introduced into rice, among other crops. This work is being done in conjunction with Arcadia Biosciences. In addition, Bayer CropScience, Pioneer Hi-Bred, BASF, and Dow, among others, are conducting research on maize, cotton, canola, and rice to develop a new generation of stress-tolerant, high-performance crop varieties. Clearly, stress-tolerant traits are of paramount importance in LDCs, especially sub-Saharan Africa and Asia. Major efforts are already underway on this front. The partnership, known as Water Efficient Maize for Africa (WEMA), was formed in response to a growing call by African farmers, leaders, and scientists to address the devastating effects of drought on small-scale farmers (Foundation, 2007). Frequent drought leads to crop failure, hunger, and poverty, which climate change can only aggravate.

At the other end of the spectrum of climate change impact is flooding due to changing rain patterns and rising sea levels. This is already a major cause of rice crop loss. It is estimated that 4 million tonnes of rice are lost every year because of flooding, which is sufficient to feed 30 million people. Rice is not grown in flooded fields through necessity but rather to control weeds; however, most rice varieties die after more than 3 days of complete submergence. Researchers know of at least one rice variety FR13A that can tolerate flooding for longer periods, but conventional breeding failed to create an event that was acceptable to farmers. The Ronald laboratory at UC Davis cloned the submergence tolerance (*Sub1*) locus from this resistance variety using a map-based cloning approach (Jung, 2010). The *Sub1* locus encodes three putative transcription regulators, one of which (*Sub 1A-1*) increases dramatically in response to oxygen deprivation in *sub1* seedlings, whereas *Sub1C* levels decrease. Transgenic lines overexpressing the *Sub1A-1* gene have been introgressed into a submergence-intolerant line and display enhanced submergence tolerance.

There is also some research in the final abiotic stress focus area, namely expansion of crops into and increased yield in less desirable and marginal soils. For example, a gene that produces citric acid in roots can protect plants from soils contaminated with aluminum, as it binds to the contaminant preventing uptake by the root system (Lopez-Bucio, 2000). Genes such as these can allow crops to be cultivated in hostile soils and temperatures, increasing geographic range while reducing potential impact on fragile ecosystems.

Increased Nutrient Content

The first generation of the products commercialized from biotechnology were crops focusing largely on input agronomic traits primarily in response to biotic stress. The coming generations of crop plants can be generally grouped into four broad areas. The present and future focus is on continuing improvement of agronomic traits such as yield and abiotic stress resistance, in addition to the biotic stress tolerance of the present generation; crop plants as biomass feedstocks for biofuels and 'bio-synthetics;' value-added output traits such as improved nutrition and food functionality; and plants as production factories for therapeutics and industrial products. Developing and commercializing plants with these improved traits involve overcoming a variety of technical, regulatory, and perception challenges inherent in perceived and real challenges of complex modifications. Both the panoply of traditional plant-breeding tools and modern biotechnology-based techniques will be required to produce plants with the desired quality traits. **Table 1** presents examples of crops that have already been GM with macro- and micronutrient traits which may provide nutritional benefits.

Although the correlative link between food and health, beyond meeting basic nutrition requirements, has only been unequivocally proven in a number of cases, a growing body of evidence indicates that food components can influence physiological processes at all stages of life. Nutrition intervention from a functionality perspective has a personal dimension. Determining individual response is at least as complex a challenge as the task of increasing or decreasing the amount of a specific protein, fatty acid, or other component of the plant itself (Brigelius-Flohe and Joost, 2006). There is also

Table 1 Examples of crops in research and development with nutritionally improved traits intended to provide health benefits for consumers and animals[a]

Trait	*Crop (trait detail)*	*References*
Proteins and amino acids		
Protein quality and level	Bahiagrass (protein↑)	Luciani *et al.*, 2005
	Canola (amino acid composition)	Roesler *et al.*, 1997

evidence that early food regimes can affect health in later life, for example, some children that survived famine conditions in certain regions of Africa grew into adults battling obesity and related problems presumably due to the selective advantage of the thrifty gene in their early food-stressed environment becoming a hazard during more abundant times, especially if later diets are calorie dense.

Functional food components are of increasing interest in the prevention and/or treatment of a number of the leading causes of death, including but not limited to cancer, diabetes, cardiovascular disease, and hypertension. Many food components are known to influence the expression of both structural genes and transcription factors in humans (Go *et al.*, 2005; Mazzatti *et al.*, 2008). Examples of these phytochemicals are listed in **Table 2** (reviewed in Newell-McGloughlin, 2010). The large diversity of phytochemicals suggests that the potential impact of phytochemicals and functional foods on human and animal health is worth examining as targets of biotechnology efforts. From a health perspective, plant components of dietary interest can be broadly divided into four main categories, which can be further broken down into positive and negative attributions for human nutrition, macronutrients (proteins, carbohydrates, lipids (oils), and fiber), micronutrients (vitamins, minerals, and phytochemicals), anti-nutrients (substances such as phytate that limit bioavailability of nutrients), allergens, intolerances, and toxins.

There are approximately 25 000 metabolites (phytochemicals), of the 200 000 or so produced by plants, with known effect in the human diet (Go *et al.*, 2005). Analysis of these metabolites (most specifically metabolomic analysis) is a valuable tool in better understanding of what has occurred during crop domestication (lost and silenced traits) and in designing new paradigms for more targeted crop improvement that is better tailored to current needs (Hall *et al.*, 2008). In addition, with modern techniques, we have the potential to seek out, analyze, and introgress traits of value that were limited in previous breeding strategies. Research to improve the nutritional quality of plants has historically been limited by a lack of basic knowledge of plant metabolism and the challenge of resolving the complex interactions of thousands of metabolic pathways. Complementary techniques, both traditional and novel, are needed to metabolically engineer plants to produce desired quality traits. Metabolic engineering is generally defined as the redirection of one or more reactions (enzymatic or otherwise) to improve the production of existing compounds to produce new compounds or mediate the degradation of undesirable compounds. It involves the redirection of cellular activities by the modification of the enzymatic, transport, and regulatory functions of the cell. Significant progress has been made in recent years in the molecular dissection of many plant pathways and in the use of cloned genes to engineer plant metabolism.

Although progress in dissecting metabolic pathways and our ability to manipulate gene expression in GM plants has progressed apace, attempts to use these tools to engineer plant metabolism have not. As the success of this approach hinges on the ability to change host metabolism, its continued development depends critically on a far more sophisticated knowledge of plant metabolism, especially the nuances of interconnected cellular networks, than what currently exists. This complex interconnectivity is regularly demonstrated. Relatively, minor genomic changes (point mutations and single-gene insertions) are regularly observed following metabolomic analysis, to lead to significant changes in biochemical composition (Bino *et al.*, 2005; Davidovich-Rikanati *et al.*, 2007; Long *et al.*, 2006). Giliberto *et al.* (2005) used a genetic modification approach to study the mechanism of light influence on antioxidant content (anthocyanin and lycopene) in the tomato cultivar Moneymaker. However, other than what on the surface would appear to be more significant, genetic changes unexpectedly yield little phenotypical effect (Schauer and Fernie, 2006).

Likewise, unexpected outcomes are often observed, for example, significant modifications made to primary Calvin cycle enzymes (fructose1,6-bisphosphatase, and phosphoribulokinase) have little effect, whereas modifications to minor enzymes (e.g., aldase, which catalyzes a reversible reaction),

Table 2 Examples of plant components with suggested functionality[a]

Class/components	*Source*[b]	*Potential health benefits*
Carotenoids		
Alpha-carotene	Carrots	Neutralizes free radicals that may cause damage to cells
Beta-carotene	Various fruits and vegetables	Neutralizes free radicals
Lutein	Green vegetables	Contributes to maintenance of healthy vision
Lycopene	Tomatoes and tomato products (ketchup and sauces)	May reduce risk of prostate cancer
Zeaxanthin	Eggs, citrus, and maize	Contributes to maintenance of healthy vision
Dietary fiber		
Insoluble fiber	Wheat bran	May reduce risk of breast and/or colon cancer
Beta glucan[c]	Oats	May reduce risk of cardiovascular disease (CVD)
Soluble fiber[c]	Psyllium	May reduce risk of CVD
Whole grains[c]	Cereal grains	May reduce risk of CVD
Collagen hydrolysate	Gelatin	May help to improve some symptoms associated with osteoarthritis
Fatty acids		
Omega-3 fatty acids – docosahexaenoic acid/ eicosapentaenoic acid	Tuna; fish and marine oils	May reduce risk of CVD and improve mental and visual functions
Conjugated linoleic acid	Cheese and meat products	May improve body composition and may decrease risk of certain cancers
Gamma linolenic acid	Borage and evening primrose	May reduce inflammation risk of cancer, CVD disease, and improve body composition
Flavonoids		
Anthocyanidins: cyanidin	Berries	Neutralize free radicals and may reduce risk of cancer
Hydroxycinnamates	Wheat	Antioxidant-like activities and may reduce risk of degenerative diseases
Flavanols: catechins, and tannins	Tea (green and catechins), (black and tannins)	Neutralize free radicals and may reduce risk of cancer
Flavanones	Citrus	Neutralize free radicals and may reduce risk of cancer
Flavones: quercetin	Fruits/vegetables	Neutralize free radicals and may reduce risk of cancer
Glucosinolates, Indoles, and Isothiocyanates		
Sulphoraphane	Cruciferous vegetables (broccoli and kale) and horseradish	Neutralizes free radicals and may reduce risk of cancer
Phenolics		
Stilbenes – Resveratrol	Grapes	May reduce risk of degenerative diseases, heart disease, and cancer; may have longevity effect
Caffeic acid and Ferulic acid	Fruits, vegetables, and citrus	Antioxidant-like activities; may reduce risk of degenerative diseases, heart disease, and eye disease
Epicatechin	Cacao	Antioxidant-like activities; may reduce risk of degenerative diseases and heart disease
Plant Stanols/sterols		
Stanol/sterol ester[c]	Maize, soy, wheat, and wood oils	May reduce risk of coronary heart disease (CHD) by lowering blood cholesterol levels
Prebiotic/probiotics		
Fructans, Inulins, and Fructooligosaccharides (FOS)	Jerusalem artichokes, shallots, and onion powder	May improve gastrointestinal health
Lactobacillus	Yogurt and other dairy	May improve gastrointestinal health
Saponins	Soybeans, soy foods, and soy protein-containing foods	May lower LDL cholesterol; contains anticancer enzymes
Soybean Protein	Soybeans and soy-based foods	25 g day^{-1} may reduce risk of heart disease

(*Continued*)

Table 2 Continued

Class/components	*Source*[b]	*Potential health benefits*
Phytoestrogens		
Isoflavones – Daidzein and Genistein	Soybeans and soy-based foods	May reduce menopause symptoms, such as hot flashes, reduce osteoporosis, and CVD
Lignans	Flax, rye, and vegetables	May protect against heart disease and some cancers; may lower LDL cholesterol, total cholesterol, and triglycerides
Sulfides/thiols		
Diallyl sulfide	Onions, garlic, olives, leeks, and scallions	May lower LDL cholesterol, helps to maintain healthy immune system
Allyl methyl trisulfide and Dithiolthiones	Cruciferous vegetables	May lower LDL cholesterol and helps to maintain healthy immune system
Tannins		
Proanthocyanidins	Cranberries, cranberry products, cocoa, chocolate, and black tea	May improve urinary tract health May reduce risk of CVD and high blood pressure

[a]Examples are not an all-inclusive list.

Nutritional and safety assessments of foods and feeds nutritionally improved through biotechnology: An executive summary. Journal of Food Science 69, CRH62–CRH68.

seemingly irrelevant to pathway flux, have major effects (Hajirezaei *et al.*, 1994; Paul *et al.*, 1995). These observations demonstrate that caution must be exercised when extrapolating individual enzyme kinetics to the control of flux in complex metabolic pathways. With evolving 'omics' tools, a better understanding of the global effects of metabolic engineering on metabolites, enzyme activities, and fluxes is beginning to be developed. Attempts to modify storage proteins or secondary metabolic pathways have also been more successful than have alterations of primary and intermediary metabolism (Della Penna, 2006). Although offering many opportunities, this plasticity in metabolism complicates potential routes to the design of new, improved crop varieties. Regulatory oversight of engineered products has been designed to detect such unexpected outcomes in biotechnology crops and, as demonstrated by Chassy *et al.* (ILSI, 2004a,b, 2008) existing analytical and regulatory systems are adequate to address novel metabolic modifications in nutritionally improved crops.

A number of new approaches are being developed to counter some of the complex problems in metabolic engineering of pathways. Such approaches include use of RNA interference (RNAi) to modulate endogenous gene expression or the manipulation of transcription factors (Tfs) that control networks of metabolism (Kinney, 1998; Bruce *et al.*, 2000; Butelli *et al.*, 2008; Gonzali *et al.*, 2009). For example, expression in tomato of two selected Tfs involved in anthocyanin production in snapdragon (*Antirrhinum majus* L.) led to high levels of these flavonoids throughout the fruit tissues, which, as a consequence, were purple. They also stimulated genes involved in the side-chain modification of the anthocyanin pigments and genes possibly related to the final transport of these molecules into the vacuole processes that are both necessary for the accumulation of anthocyanin (Gonzali *et al.*, 2009). Such expression experiments hold promise as an effective tool for the determination of transcriptional regulatory networks for important biochemical pathways. Gene expression can be modulated by numerous transcriptional and posttranscriptional processes. Correctly choreographing the many variables is the factor that makes metabolic engineering in plants so challenging.

In addition, there are several new technologies that can overcome the limitation of single-gene transfers and facilitate the concomitant transfer of multiple components of metabolic pathways. One example is multiple-transgene direct DNA transfer, which simultaneously introduces all the components required for the expression of complex recombinant macromolecules into the plant genome as demonstrated by a number of studies, including Nicholson *et al.* (2005), who successfully delivered four transgenes that represent the components of a secretory antibody into rice. Carlson *et al.* (2007) constructed a minichromosome vector that remains autonomous from the plant's chromosomes and stably replicates when introduced into maize cells. This work makes it possible to design minichromosomes that carry cassettes of genes, enhancing the ability to engineer plant processes, such as the production of complex biochemicals. Naqvi *et al.* (2009) demonstrated that gene transfer using minimal cassettes is an efficient and rapid method for the production of transgenic plants stably expressing several different transgenes. As no vector backbones are required, this prevents the integration of potentially recombinogenic sequences, insuring stability across generations. They used combinatorial direct DNA transformation to introduce multi-complex metabolic pathways coding for beta-carotene, vitamin C, and folate. They achieved this by transferring five constructs controlled by different endosperm-specific promoters into white maize. Different enzyme combinations show distinct metabolic

phenotypes resulting in 169 fold beta-carotene increase, six times the amount of vitamin C, and doubling folate production effectively, creating a multivitamin maize cultivar (Naqvi *et al.*, 2009). This system has an added advantage from a commercial perspective in that these methods circumvent problems with traditional approaches that not only limit the amount of sequences transferred but may also disrupt native genes or lead to poor expression of the transgene, thus reducing both the numbers of transgenic plants that must be screened and the subsequent breeding and introgression steps required to select a suitable commercial candidate.

As demonstrated, 'omics'-based strategies for gene and metabolite discovery, coupled with high-throughput transformation processes and automated analytical and functionality assays, have accelerated the identification of product candidates. Identifying rate-limiting steps in synthesis could provide targets for modifying pathways for novel or customized traits. Targeted expression are used to channel metabolic flow into new pathways, whereas gene-silencing tools reduce or eliminate undesirable compounds or traits or switch off genes to increase desirable products (Davies, 2007; Liu, 2002; Herman, 2003). In addition, molecular marker-based breeding strategies have already been used to accelerate the process of introgressing trait genes into high-yielding germplasm for commercialization. **Table 1** summarizes the work being undertaken to date on specific applications in the categories listed above. The following sections briefly review some examples under those categories.

Macronutrients: Protein

The FAO estimates that 850 million people worldwide suffer from undernutrition, of which insufficient protein in the diet is a significant contributing factor (FAO, 2004, 2011). Protein–energy malnutrition is the most lethal form of malnutrition and affects every fourth child worldwide according to the WHO (2006). Most plants have a poor balance of essential amino acids relative to the needs of animals and humans. The cereals (maize, wheat, rice, etc.) tend to be low in lysine, whereas legumes (soybean and peas) are often deficient in the sulfur-rich amino acids, methionine and cysteine. Successful examples of improving amino acid balance to date include high-lysine maize (Eggeling *et al.*, 1998; O'Quinn *et al.*, 2000) canola, and soybeans (Falco *et al.*, 1995). Free lysine is significantly increased in high-lysine maize by the introduction of the *dapA* gene (*cordapA*) from *Corynebacterium glutamicum*, which encodes a form of dihydrodipicolinate synthase that is insensitive to lysine feedback inhibition. Consumption of foods made from these crops potentially can help to prevent malnutrition in developing countries, especially among children.

Another method of modifying storage protein composition is to introduce hetero- or homologous genes that code for proteins containing elevated levels of the desired amino acid, such as the sulfur-containing amino acids (methionine and cysteine) or lysine. An interesting solution to this is to create a completely artificial protein containing the optimum number of the essential amino acids methionine, threonine, lysine, and leucine in a stable, helical conformation designed to resist proteases to prevent degradation. This was achieved by a number of investigations, including sweet potato modified with an artificial storage protein (*ASP-1*) gene (Prakash *et al.*, 2000). These transgenic plants exhibited a two- and fivefold increase in the total protein content in leaves and roots, respectively, over that of control plants. A significant increase in the level of essential amino acids, such as methionine, threonine, tryptophan, isoleucine, and lysine, was also observed (Prakash *et al.*, 2000; ILSI, 2008). A key issue is to insure that the total amount and composition of storage proteins is not altered to the detriment of the development of the crop plant when attempting to improve amino acid ratios (Rapp *et al.*, 2002).

Some novel indirect approaches have also been taken to improve protein content. Uauy *et al.* (2006) 'rescued' an ancestral wheat allele that encodes a transcription factor (*NAM-B1*) which accelerates senescence and increases nutrient remobilization from leaves to developing grains (modern wheat varieties carry a nonfunctional allele.) Reduction in RNA levels of the multiple *NAM* homologs by RNAi delayed senescence by more than 3 weeks and reduced wheat grain protein, zinc, and iron content by more than 30%. Young *et al.* (2004) used yet another approach to indirectly increase protein and oil content. They used a bacterial cytokinin-synthesizing isopentenyl transferase (IPT) enzyme, under the control of a self-limiting senescence-inducible promoter, to block the loss of the lower floret resulting in the production of just one kernel composed of a fused endosperm with two viable embryos. The presence of two embryos in a normal-sized kernel leads to displacement of endosperm growth, resulting in kernels with an increased ratio of embryo to endosperm content. The end result is maize with more protein and oil and less carbohydrate (Young *et al.*, 2004; ILSI, 2008).

Macronutrients: Fiber and Carbohydrates

Fiber is a group of substances chemically similar to carbohydrates that nonruminant animals, including humans, poorly metabolize for energy or other nutritional uses. Fiber provides bulk in the diet such that foods rich in fiber offer satiety without contributing significant calories. Current controversies aside, there is ample scientific evidence to show that prolonged intake of dietary fiber has various positive health benefits, especially the potential for reduced risk of colon and other types of cancer.

Recent microbiome twin studies addressing the interrelationships between diet and gut microbial community structure/function indicated that differences in our gut microbial ecology affect our predisposition to obesity or malnutrition and that diet rather than applied probiotics was the single most important characterization of gut health (Turnbaugh, 2009). These studies involved characterization of the gut microbiota/microbiome of twins, concordant or discordant for malnutrition, living in several developing countries, who are sampled just before, during, and after treatment.

When such colonic bacteria (especially Bifidobacteria) ferment dietary fiber or other unabsorbed carbohydrates, the products are short-chain saturated fatty acids. These short-chain fatty acids may enhance absorption of minerals such as

iron, calcium, and zinc; induce apoptosis preventing colon cancer; and inhibit 3-hydroxy-3-methylglutaryl coenzyme-A reductase (HMG-CoAR), thus lowering low-density lipoprotein (LDL) production (German, 2005). Plants are effective at making both polymeric carbohydrates (e.g., starches and fructans) and individual sugars (e.g., sucrose and fructose). The biosynthesis of these compounds is sufficiently understood to allow the bioengineering of their properties and to engineer crops to produce polysaccharides not normally present. Polymeric carbohydrates such as fructans have been produced in sugar beet and inulins and amylase (resistant starch) in potato (Hellwege *et al.*, 2000) without adverse effects on growth or phenotype. A similar approach is being used to derive soybean varieties that contain some oligofructan components that selectively increase the populations of beneficial bacterial species in the intestines of humans and certain animals while inhibiting the growth of harmful ones (Bouhnik, 1999).

Macronutrients: Novel Lipids

Genomics-based approaches, specifically marker-assisted plant breeding, combined with recombinant DNA technology provide powerful means for modifying the composition of oilseeds to improve their nutritional value and provide the functional properties required for various food oil applications. Genetic modification of oilseed crops can provide an abundant, relatively inexpensive source of dietary fatty acids with wide ranging health benefits. The production of such lipids in vegetable oil provides a convenient mechanism to deliver healthier products to consumers without the requirement for significant dietary changes. Major alterations in the proportions of individual fatty acids have been achieved in a range of oilseeds using conventional selection, induced mutation, and, more recently, posttranscriptional gene silencing (PTGS). Examples of such modified oils include: low- and zero-saturated fat soybean and canola oils; canola oil containing medium-chain fatty acids whose ergogenic potential may have application in LDCs; high stearic acid canola oil (for trans fatty acid-free products); high oleic acid (monounsaturated) soybean oil; canola oil containing the polyunsaturated fatty acids (PUFA) and gamma-linolenic acid (GLA; 18:3 n-6); and soybean oils containing stearidonic acids (SDA; C18:4 n-3) (SDA, 2011), very long-chain fatty acids (Zou *et al.*, 1997), and omega-3 fatty acids (Yuan and Knauf, 1997; SDA, 2011). These modified oils are being marketed and many countries have a regulatory system in place for the premarket safety review of novel foods produced through conventional technology.

Edible oils rich in monounsaturated fatty acids provide improved oil stability, flavor, and nutrition for human and animal consumption. High-oleic soybean oil is naturally more resistant to degradation by heat and oxidation, and so requires little or no post-refining processing (hydrogenation), depending on the intended vegetable oil application. Oleic acid (18:1), a monounsaturate, can provide more stability than the polyunsaturates, linoleic (18:2) and linolenic (18:3) acids. Antisense inhibition of oleate desaturase expression in soybean resulted in oil that contained >80% oleic acid (23% is normal) and had a significant decrease in PUFA (Kinney and Knowlton, 1998). DuPont has introduced soybean oil composed of at least 80% oleic acid, approximately 3% linolenic acid, and more than 20% less-saturated fatty acids than commodity soybean oil. Monsanto's Vistive contains less than 3% linolenic acid, compared with 8% for traditional soybeans, which results in more stable soybean oil and less need for hydrogenation.

A key function of α-linolenic acid is as a substrate for the synthesis of longer chain ω-3 fatty acids, found in fish, eicosapentaenoic acid (EPA; C20:5n-3), and docosahexaenoic acid (DHA; C22:6n-3), which play an important role in the regulation of inflammatory immune reactions and blood pressure, brain development *in utero*, and, in early postnatal life, the development of cognitive function. Stearidonic acid (SDA, C18:4n-3), EPA, and DHA also possess anticancer properties (Reiffel and McDonald, 2006; Christensen JH *et al.*, 1999; Smuts, 2003). Research indicates that the ratio of n-3 to n-6 fatty acids may be as important to health and nutrition as the absolute amounts present in the diet or in body tissues. Current Western diets tend to be relatively high in n-6 fatty acids and relatively low in n-3 fatty acids. Production of a readily available source of long-chain PUFA, specifically ω-3 fatty acids, delivered in widely consumed prepared foods could deliver much needed ω-3-fatty acids to large sectors of the population with skewed n-6:n-3 ratios. In plants, the microsomal ω-6 desaturase-catalyzed pathway is the primary route of production of polyunsaturated lipids. Ursin *et al.* (2000, 2003) had introduced the delta-6 desaturase gene from a fungus (*Mortierella* sp.), succeeding in producing omega-3 in canola. In subsequent work the same gene was added to soybean and transgenic soybean oil was obtained that contained >23% SDA, with an overall n-6: n-3 ratio of 0.5, which the body converts to heart-healthy eicosapentaenoic acid (EPA), one of three omega-3 fatty acids used by the body. This product is now being developed for commercialization by Monsanto (SDA, 2011).

However, not all omega-6 fatty acids are created equal. GLA, C18:3n-6 is an omega-6 fatty acid with health benefits that are similar and complementary to the benefits of omega-3 fatty acids, including anti-inflammatory effects, improved skin health, and weight loss maintenance (Schirmer *et al.*, 2007). Davis, CA company, Arcadia has engineered GLA safflower oil, with up to 40% GLA, essentially quadrupling the levels obtained in source plants such as evening primrose and borage (Arcadia Biosciences, 2008). Structural lipids also have positive health benefits; for example, in addition to their effect in lowering cholesterol, membrane lipid phytosterols have been found to inhibit the proliferation of cancer cells by inducing apoptosis and G1/S cell cycle arrest through the HMG-CoAR as noted above (Awad, 2000). In addition, specialty oils may also be developed with further pharmaceutical and chemical feedstock applications in mind.

Micronutrients: Vitamins and Minerals

Micronutrient malnutrition, the so-called hidden hunger, affects more than one-half of the world's population, especially women and preschool children in developing countries (UN

SCN, 2004). Even mild levels of micronutrient malnutrition may damage cognitive development and lower disease resistance in children and increase incidences of childbirth mortality. The costs of these deficiencies, in terms of diminished quality of life and lives lost, are large (Pfeiffera and McClafferty, 2007). Such deficiencies prevent children from reaching their full potential as adults; malnutrition, especially during the 1000 days between pregnancy and age 2 years, can lead to irreversible physical stunting and cognitive impairment. However, children who are well nourished are able to grow, learn, and prosper. They achieve more in school, are better able to survive illnesses, and tend to earn more as adults (Kraemer, 2012). The clinical and epidemiological evidence is clear that select minerals (iron, calcium, selenium, and iodine) and a limited number of vitamins (folate, vitamins E, B_6, and A) play a significant role in maintenance of optimal health and are limiting in diets (Asensi-Fabado, 2010).

As with macronutrients, one way to ensure an adequate dietary intake of nutritionally beneficial phytochemicals is to adjust their levels in plant foods. Using various approaches, including genomics, vitamin E levels are being increased in several crops, including soybean, maize, and canola, whereas rice varieties are being developed with the enhanced vitamin A precursor, beta-carotene, to address vitamin A deficiency that leads to macular degeneration and impacts development. Golden Rice II accumulates up to 37 μg of beta-carotene per gram of rice (23-fold more than the original). This beta-carotene has been shown to be bioavailable in sufficient amounts that 100–200 g per day can provide adequate pro-vitamin A to ameliorate against deficiency (Tang *et al.*, 2009). It is estimated that Golden rice will finally be approved for commercialization in the Philippines by 2014. A number of other staple crops on which many depend almost exclusively for calories have been produced enriched in beta-carotene, including maize, cassava, millet, and sorghum (Harjes *et al.*, 2008; Welsch *et al.*, 2010; Yan *et al.*, 2010). Cassava is being field tested in Nigeria. Ameliorating another major deficiency in LDCs, namely minerals such as iron and zinc, has also been addressed. Iron is the most commonly deficient micronutrient in the human diet, and iron deficiency affects an estimated 1 to 2 billion people. Anemia, characterized by low hemoglobin, is the most widely recognized symptom of iron deficiency, but there are other serious problems, such as impaired learning ability in children, increased susceptibility to infection, and reduced work capacity. Drakakaki *et al.* (2005) demonstrated endosperm-specific co-expression of recombinant soybean ferritin and *Aspergillus fumigatus* phytase in maize, which resulted in significant increases in the levels of bioavailable iron. A similar end was also achieved with lettuce (Goto *et al.*, 2000). The Africa Biofortified Sorghum (ABS) Project developed the world's first sorghum transformation system as well as the first 'golden' sorghum that had elevated provitamin A levels, reduced phytate, raised grain protein profile, and raised absorbability of zinc and iron (Blaine, 2011).

A rather interesting approach was taken by Connolly *et al.* (2008) to increase the levels of calcium in crop plants by using a modified calcium (Ca)/proton antiporter (known as short cation exchanger 1 (sCAX1) to increase Ca transport into vacuoles. They also demonstrated that consumption of such Ca-fortified carrots results in enhanced Ca absorption. This demonstrates the potential of increasing plant nutrient content through expression of a high-capacity transporter and illustrates the importance of demonstrating that the fortified nutrient is bioavailable. Other targets include folate-enriched tomatoes and isoflavonoids (Yonekura-Sakakibara and Saito, 2007; DellaPenna, 2007).

Micronutrients: Phytochemicals

Unlike for vitamins and minerals, the primary evidence for the health-promoting roles of phytochemicals comes from epidemiological studies, and the exact chemical identity of many active compounds has yet to be determined. However, for select groups of phytochemicals, such as non-provitamin A carotenoids, glucosinolates, and phytoestrogens, the active compound or compounds have been identified and rigorously studied. Epidemiologic studies have suggested a potential benefit of the carotenoid lycopene in reducing the risk of prostate cancer, particularly the more lethal forms of this cancer. Five studies support a 30–40% reduction in risk associated with high tomato or lycopene consumption in the processed form in conjunction with lipid consumption, although other studies with raw tomatoes were not conclusive (Giovannucci, 2002). As carotenoids are lipid soluble and cooking breaks down carotenoid-binding proteins, this is not an unexpected outcome. In a study by Mehta *et al.* (2002) to modify polyamines to retard tomato ripening they found an unanticipated enrichment in lycopene with levels up by 2- to 3.5-fold compared with conventional tomatoes. This is a substantial enrichment, exceeding that so far achieved by conventional means. This approach may work in other fruits and vegetables. Flavonoids meanwhile are soluble in water, and foods containing both water-soluble and fat-dissolved antioxidants are considered to offer the best protection against disease. Anthocyanins offer protection against certain cancers, cardiovascular disease, and age-related degenerative diseases. There is evidence that anthocyanins also have anti-inflammatory activity, promote visual acuity, and hinder obesity and diabetes. Both Gonzali *et al.* (2009) and Butelli *et al.* (2008) used snapdragon transcription factors to achieve high levels of the reactive oxygen scavengers, anthocyanins expression in tomatoes. In a pilot test, the lifespan of cancer-susceptible mice was significantly extended when their diet was supplemented with the purple tomatoes compared with supplementation with normal red tomatoes.

Other phytochemicals of interest include related polyphenolics such as resveratrol, which has been demonstrated to inhibit platelet aggregation and eicosanoid synthesis in addition to protecting the sirtuins, genes implicated in DNA modification and life extension; flavonoids, such as tomatoes expressing chalcone isomerase that show increased contents of the flavanols rutin and kaempferol glycoside; glucosinolates and their related products, such as indole-3 carbinol (I3C); catechin and catechol; isoflavones, such as genistein and daidzein; anthocyanins; and some phytoalexins. **Table 1** summarizes activities in improving nutritional characteristics of various crops worldwide. A comprehensive list of phytochemicals are outlined in **Table 2** (reviewed in Newell-McGloughlin, 2010). To reiterate, although there is a growing

knowledge base indicating that elevated intakes of specific phytochemicals may reduce the risk of diseases, such as certain cancers, cardiovascular diseases, and chronic degenerative diseases associated with aging, further research and epidemiological studies are still required to prove definitive relationships.

Protecting Plants

Plants produce many defense strategies to protect themselves from predators. Many, such as resveratrol and glucosinate, which are primarily pathogen-protective chemicals, also have demonstrated beneficial effects for human and animal health. Many, however, have the opposite effect. For example, phytate, a plant phosphate storage compound, is considered an anti-nutrient as it strongly chelates iron, calcium, zinc, and other divalent mineral ions, making them unavailable for uptake. Nonruminant animals generally lack the phytase enzyme needed for digestion of phytate. Poultry and swine producers add processed phosphate to their feed rations to counter this. Excess phosphate is excreted into the environment, resulting in water pollution. When low-phytate soybean meal is utilized along with low-phytate maize for animal feeds the phosphate excretion in swine and poultry manure is halved. A number of groups have added heat- and acid-stable phytase from *A. fumigatus* inter alia to make the phosphate and liberated ions bioavailable in several crops (Potrykus, 1999). To promote the reabsorption of iron, a gene for a metallothionein-like protein has also been engineered. Low-phytate maize was commercialized in the United States in 1999 (Wehrspann, 1998).

In November 2009, the Chinese company Origin Agritech announced the final approval of the world's first GM phytase-expressing maize (Han, 2009). Research indicates that the protein in low-phytate soybeans is also slightly more digestible than the protein in traditional soybeans. In a poultry-feeding trial, better results were obtained using transgenic plant material than with the commercially produced phytase supplement (Keshavarz, 2003). Poultry grew well on an engineered alfalfa diet without any inorganic phosphorus supplement, which shows that plants can be tailored to increase the bioavailability of this essential mineral. A similar effect was achieved in wheat by a Danish group where temperature-tolerant phytase resisted boiling (Brinch-Pedersen *et al.*, 2006).

One of the first products modified for safety was submitted for petition for determination of nonregulated status in 2013. The submission was by JR Simplot for a potato that has three specific modifications for quality improvement. They use what they term 'Innate' technology, basically utilizing RNAi (to silence genes related to expression of black spot bruise, asparagine, and reducing sugars in tubers).

The three traits modified are important from a commercial perspective as they greatly improve the quality of the potato, making them more appealing to both producers and consumers. The first of those traits, reduced black spot from bruising and browning, is achieved through RNAi suppression of PPO effectively reducing oxidation by silencing the endogenous PPO gene. Not alone is this more appealing for the consumer, it will help to reduce waste for growers as fewer potatoes will be discarded.

The second is a reduction in reducing sugars through downregulation of phosphorylase and starch-associated genes slowing the conversion to sucrose and fructose, which provides potatoes with a consistent golden color resulting in improved taste and texture qualities.

The third is suppression of asparagine through expression of asparagine synthetase-1, which reduces the potential for the formation of acrylamide by 80%. The latter is created when potatoes are cooked at high temperatures. In addition, the reducing sugars react with amino acids, such as asparagine, to produce Maillard products, including acrylamide. So by reducing the levels of these sugars and asparagine in stored potatoes, they can significantly reduce the levels of acrylamide in the food. Accordingly, this modification improves not only the quality but also the safety of the potato by reducing the levels of this toxic chemical.

Expression of the first cassette lowers transcript levels for the asparagine synthetase-1 (Asn1) and polyphenol oxidase-5 (Ppo5) genes and, consequently, limits the formation of the acrylamide precursor asparagine and the formation of impact-induced black spot bruise that occurs when the enzyme PPO oxidizes phenols to produce dark pigments. The presence of black spot bruise results in lower quality and subsequent production losses during processing into fries or chips.

A reduction in the formation of reducing sugars is accomplished by the downregulated transcript levels for the PhL (phosphorylase-L) and R1 (starch associated) genes resulting from expression of the second cassette. These traits function by slowing the conversion of starch to reducing sugars (glucose and fructose). Benefits include improved quality, especially relating to color control, and thus contributing to the desired golden brown colors required by most French fry or chip customers. Also, the reducing sugars react with amino acids, such as asparagine, to produce Maillard products, including acrylamide. So by reducing the levels of these sugars in stored potatoes, we can significantly reduce the levels of toxic acrylamide in the food.

Other anti-nutrients that are being examined as possible targets for reduction are trypsin inhibitors, lectins, and several heat-stable components found in soybeans and other crops. Likewise, strategies are being employed to reduce or limit food allergens (albumins, globulins, etc.), malabsorption, and food intolerances (gluten) and toxins (glycoalkaloids, cyanogenic glucosides, and phytohemagglutinins) in crop plants and aesthetic undesirables, such as caffeine (Ogita, 2003). Examples include changing the levels of expression of the thioredoxin gene to reduce the intolerance effects of wheat and other cereals (Buchanan, 1997) and using RNAi to silence the major allergen in soybeans (P34 a member of the papain superfamily of cysteine proteases) and rice (14–16 kDa allergenic proteins). Blood serum tests indicate that p34-specific IgE antibodies could not be detected after consumption of gene-silenced beans (Helm, 2000; Herman, 2003).

Modern biotechnology approaches can be employed to downregulate or even eliminate the genes involved in the metabolic pathways for the production, accumulation, and activation of these toxins in plants. For example, the solanine content of potato has already been reduced substantially using an antisense approach, and efforts are underway to reduce the level of the other major potato glycoalkaloid, chaconine

(McCue *et al.*, 2003). Work has also been done to reduce cyanogenic glycosides in cassava through expression of the cassava enzyme hydroxynitrile lyase in the roots (Siritunga and Sayre, 2003). When 'disarming' plants' natural defenses in this way one must be aware of potentially increased susceptibility to pests, diseases, and other stressors, so that the recipient germplasm should have input traits to counter this.

Improvement of crop nutritional quality is a technical challenge hampered by a lack of basic knowledge of plant metabolism and the need to resolve the complexity of intersecting networks of thousands of metabolic pathways. With the tools now available through the field of genomics, proteomics, lipomics, glycobiomics, metabolomics, and bioinformatics, we have the potential to study and manipulate genes and pathways at the metalevel while simultaneously studying the expression and interaction of transgenes on tens of thousands of endogenous genes. With these newly evolving tools we are beginning to dissect the global effects of metabolic engineering on metabolites, enzyme activities, and fluxes. For essential macro- and micronutrients that are limiting in various regional diets, the strategies for improvement are clear and the concerns, such as pleiotropic effects and safe upper limits, are easily addressed. However, for many putative health-promoting phytochemicals, clear links with health benefits are yet to be demonstrated. In addition, one must be careful when extrapolating attributes from an individual substance acting independently to that substance acting within a complex milieu. However, if such links can be established it will make it possible to identify the precise compound or compounds to target and which crops to modify to achieve the greatest nutritional impact and health benefit. With rapidly emerging technologies the increase in our understanding and ability to manipulate plant metabolism during the coming decades should place plant researchers in the position of being able to modify the nutritional content of major and minor crops to improve many aspects of human and animal health and well-being.

Barriers to Introduction

Commercialization of the first generation of products of recombinant DNA technology was another facet in a long history of human intervention in nature for agricultural and food production purposes. Hence, the same parameters of risk-based assessment should apply. Commercialization of products must be undertaken within a regulatory framework that ensures adequate protection of the consumer, the environment, and alternate production systems while not stymieing innovation. The first generation of such crops focused largely on input agronomic traits; the next generation will focus more on value-added output traits.

There is almost universal agreement that innovation is essential for sustaining and enhancing agricultural quality and productivity. There also would be general concurrence that this involves at some level new, science-based products and processes that contribute reliable methods for improving quality, productivity, and environmental sustainability. Most of the innovative technologies that have been applied to production agriculture have come into common usage without much controversy or even knowledge by the average consumer. However, thanks to the globalization and democratization of knowledge afforded by the internet, the cult of the amateur as noted by Trewavas (2008) is in danger of giving equal weight to uninformed opinions and blatant fearmongering when it comes to applying the tools of modern technology to improving agricultural efficiencies and enhancing food security.

In the past we have not regulated changes in agriculture based on unpredictable socioeconomic consequences. However, some recent innovative technologies, namely biotechnology and more specifically recombinant DNA technology, have inspired debate in a manner unlike any other previous technological development. Although biotechnology has introduced a new dimension to such innovation, offering efficient and cost-effective means to produce a diverse array of novel, value-added products and tools is not viewed with unmitigated beneficence by all existing and potential stakeholders. The stakeholders involved in this debate are many and diverse, ranging from academic and industrial scientists to conventional and organic producers, to international, national, federal, state, and local government organizations, NGOs and agencies, to activist groups, and ultimately consumers. How this technology is viewed depends very much on the perspective from which it is viewed and the goals and objectives of the different players involved. Individual perspectives are formed by the complexity of the prism through which the world is viewed. Each individual's prism is built of our cumulative life experiences, educational background, innate prejudices, world view, and personal objectives. Although on the surface, scientific facts may appear immutable, how those facts are presented within a socioeconomic context makes for an interesting study of the stratagems used by the diverse stakeholders to advance their own agenda for any given target demographic. These tactics are played out on local and world stages and often by the same players who customize their approach depending on the context.

To most producers, and academic and industrial researchers, biotechnology is seen as offering a new dimension to innovation, providing an efficient and cost-effective means to produce a diverse array of value-added products and tools. To some of our national and international markets it is seen as a trading barrier or chip, depending on which side of the fence one is standing. To others it represents an unnecessary, and for some, unnatural risk at a broad level to our food system and environment and at a very fundamental level to a way of life or code of beliefs. Unfortunately, as in every walk of life, there are some who seize on these many nuances of perception, and indeed fear, to propagate their own, covert or otherwise, agenda.

There is a need to address the issue of barriers that exist to commercialization. Most of the crops approved to date support the notion that the deregulation process is prohibitive for any but well-financed companies whose focus are primarily the large commodity crops as just discussed. Worldwide, there is clear asymmetry and lack of consensus in regulatory systems. Non-hypothesis-based evaluations have become the standard around the world, and these are being enshrined in the Cartagena Protocol's Roadmap, with the result that cost of safety assessment has sky rocketed without any discernible gain in safety. Given the current regulatory climate, it is difficult to

imagine many of the traits described ever reaching the marketplace. This discourages research on anything but the most mundane of crops and traits and is a real disincentive to creative research. For all intent and purposes there is just one trait from a public institution that has successfully traversed the regulatory minefields and been translated into a commercially viable commodity and that is the viral coat protein protection system initially developed for the papaya ringspot virus (PRSV) pandemic in Hawaii. Papaya is a major tropical fruit crop in the Asian region. However, production in many countries is set back by the prevalence of the PRSV disease as well as postharvest losses. The PRSV-resistant papaya, based on RNAi suppression of the coat protein expression, literally saved the US$17 million economy in Hawaii and although the disease is of significant importance in Taiwan and other SE Asian countries, it has yet to be approved. Coat protein-based resistance is a demonstration of what is known as PTGS later determined to be RNAi, as described earlier. A 20-year effort to combat plum pox virus (PPV) disease through PTGS resistance paid off. In 1990, the USDA/Agricultural Research Service (ARS) scientists began their efforts with a papaya ringspot virus coat protein gene obtained from Dennis Gonsalves. This gene shows 70% homology to the plum pox gene and has been used to control other viruses similarly related to papaya ringspot. Based on this, the USDA developed a transgenic plum line C5, which contains multiple copies of the PPV-CP transgene and is stably resistant to the virus (Scorza *et al.*, 2009) This has been deregulated by Animal and Plant Health Inspection Service (APHIS) and rather incongruously the construct within the trees is registered as a pesticide under EPA FIFRA (Federal Insecticide, Fungicide, and Rodenticide Act) and nurseries that produce them are designated 'pesticide producing establishments' (U.S. Environmental Protection Agency, 2010). However, irrespective of the mechanism, it is important that resistance based on a single gene is managed well and alternate control mechanisms are introduced to reduce pressure on the development of viral resistance. Other approaches include expression of the genes for RNA-replicating enzymes of the virus, expression of satellite RNA, replicating RNA molecules that are molecular parasites of the virus, or the use of protease inhibitors to interfere with processing of the viral proteins.

Rather interestingly, Gonsalves (2003) reported that the transgenic papaya has helped growers to raise nontransgenic papaya in Puna by reducing the overall virus pressure in Puna and serving as buffer zones, suggesting that virus-resistant transgenic crops can directly control the virus and also serve as a tool to minimize infection to nontransgenic crops that are grown in the area. It has been reported that organic papaya growers now surround their plots with the transgenic rainbow variety as the PTGS system proves to be a most effective method to reduce the viral reservoir, thus protecting susceptible varieties through a mechanism that is similar to herd immunity in mammalian systems (Summers, 2014). The late blight resistant potatoes discussed above could feasibly provide the same cooperative resistance for organic potato farmers in Europe, but as BASF has pulled its production in the European Union, this cannot now be demonstrated. Research by Hutchison *et al.* (2010) demonstrates a variation of this halo effect for Bt maize. As noted to militate against the evolution of resistance, growers are required to maintain a 20% refugium of non-Bt maize. Despite predictions that this single-gene protection may select the development of resistant in corn borer larvae on maize or bollworm in cotton, it has proven to be remarkably resilient. Although some resistance has arisen most specifically in the latter where a mutation in the cadherin receptor has led to localized resistance, it is much lower than what might be expected given the extent of usage of the Bt phenotype. Actually, although mutations providing small decreases in susceptibility to Bt proteins are relatively common, those conferring sufficient resistance to enable survival on some types of Bt corn are exceedingly rare. Hutchison (2010) had demonstrated that this had led to cumulative benefits over 14 years of between US$3.2 and US$3.6 billion with US$1.9–2.4 billion of this total accruing to non-Bt maize growers. They postulated that these results affirmed theoretical predictions of pest population suppression and highlighted economic incentives for growers to maintain non-Bt maize refugia for sustainable insect resistance management. Although initially these refugia were required to be in specified plots, it has been put forward that mixing Bt and non-Bt maize grain during planting may be an equally effective management strategy. However, this effect is disputed by some entomologists. Again, enforcement of these requirements had been relatively easy in the developed world, whereas doing so in some regions may prove more challenging.

The obdurate attitude of the European Union has consequences beyond the obvious economic. A case in point is the BASF's decision to pull the Fortuna potato as cited above. Now instead of adopting the GM Fortuna cultivar and the subsequent reduction of the use of harmful chemicals, European farmers must rely on the continued use of fungicides, which are some of the least friendly biocontrol chemicals. Ironically, as noted, this choice obstructs further expansion of organically produced potatoes and tomatoes because adopting the GM Fortuna cultivar in 'conventional' agriculture could have led to reduced disease pressures benefitting alternative farming systems (Dixelius, 2012). In addition, as a major consumer of potatoes, the European Union will now become increasingly dependent on import from other regions, as they inevitably lose the battle against *P. infestans*. Over time these imported potatoes are likely to be GM Fortuna, so Europe is still left with the problem of tackling political resistance against it or any other GM crop.

Although translation of biotechnology research into value added products for producers and consumers is a challenge in the European Union and even in the United States, it is exponentially more difficult in LDCs. A problem facing Africa in particular is the lack of a dynamic private sector to take technologies to the farmer. It has also been estimated that regulatory costs exceed the costs of research and experimentation needed to develop a given GM crop, which is a major problem in releasing such crops to the market. A way to reduce the costs of generating food and environmental safety data is to develop regional 'centers of excellence' with complementary facilities for biosecurity compliance. If this can be done reliably, then regulatory costs could be reduced. The economic gains from using GM crop technology in SSA are potentially large according to the World Bank Group (Anderson, 2005). The results suggest that the welfare gains are potentially very large,

especially from golden rice (beta-carotene-enhanced rice) and nutritionally enhanced GM wheat and that those benefits are diminished only slightly by the presence of the European Union's current ban on imports of GM foods.

Using the global economy-wide computable general equilibrium model, known as Global Trade Analysis Project (GTAP), Anderson *et al.* (2005) specifically noted that if SSA countries impose bans on GM crop imports in deference to EU market demand for non-GM products, the domestic consumer net loss from that protectionism would be more than the small gain derived from greater market access to the European Union.

In December 2012 the FAO's Director-General, José Graziano da Silva, noted that food insecurity in Africa's Sahel region is closely linked to peace and stability, and he stressed that short-term humanitarian efforts in the Sahel needed to be replaced with longer term development (da Silva, 2012). Apart from the suggested implication of food and agricultural markets as being one of the trigger factors in catalyzing the 'Arab Spring,' the most recent global food crisis was in 2008 and, as noted, we may be facing an even greater one in coming years. During this crisis, which was erroneously laid disproportionately on the shoulders of biofuel production, most especially grain ethanol, the Gates Foundation announced US$306 million in grants to boost agricultural yields in the developing world, with nearly US$165 million to replenish depleted soils in Africa. As noted by US News and World reports these efforts are not without controversy as they charge that critics consider that western philanthropists are violating African 'food sovereignty' and promoting American at the expense of peasant farmers knowledgeable about local practices (Lavelle *et al.*, 2008). But local practices have yielded scarcity. A farmer in India grows three to four times as much food on the same amount of land as a farmer in Africa; a farmer in China, roughly seven times as much. Biotechnology crops can contribute to a 'sustainable intensification' strategy favored by many science academies worldwide, which allows productivity to be increased only on the current 1.5 billion hectares of global crop land, thereby saving sensitive land and biodiversity.

Problems cited for the slow passage of GM crops from experimental, to trial, to commercial stage include the lack of capacity to negotiate licenses to use genes and research techniques patented by others, especially for crops with export potential. In addition, there are difficulties in meeting regulatory requirements and a lack of effective public commercialization modalities and working extension networks. Biosafety and Intellectual Property Rights (IPR) regulations still have to be enforced in many countries for an effective and purportedly 'safe' use of genetically engineered crops, especially if their production is intended for the export market.

As noted, intellectual property constraints continue to be a significant barrier in some regions and for some technologies. If the public sector is going to contribute in tangible ways to technological approaches for food security, the public research system needs to be optimized for translation in this arena. At the research level, this is usually not of major importance in developing regions, but at the commercialization stage this has the potential to be a significant barrier to initial adoption, but most specifically to enforcement of regulations. An additional impediment that public sector researchers often encounter is that the constructs for which they have Freedom to Operate in research applications are patent protected and must be licensed at some cost before a product can be considered for commercialization. Benchmarking standards and best of breed should be created to facilitate this type of translation. There are some entities, such as CAMBIA in Australia and the Public-Sector Intellectual Property Resource for Agriculture (PIPRA) at the University of California, Davis, which seek to assist both public and private sector crop developers to assess the IP terrain, to develop licensing and other types of agreements, and to formulate a commercialization or product release strategy for resource-poor regions (Bennett, 2010).

But what of the context in which these crops are grown? Can all cropping systems coexist in harmony? According to Brookes and Barfoot (2008), it is important to determine the relative importance of different crop production systems based on planted area, production, and economic value to the region in question. The issue is what, if any, are the economic consequences of adventitious presence of material from one crop system within another based on the notion that farmers should be able to cultivate freely the crops of their choice using whichever production system works best in any given context (GM, conventional, or organic). It is never a food or environmental safety issue but rather a production and marketing matter. The heart of the issue is assessing the likelihood of the adventitious presence of material from one production system affecting another and the potential impacts. This requires consistency when dealing with the adventitious presence of any unwanted material, including, but most definitely not limited to, biotechnology-derived material. Adventitious presence is simply the unintended incidence of something other than the desired crop, such as small quantities of weed seeds, seeds from other crops, dirt, insects, or foreign material (e.g., stones). It is unrealistic to expect 100% purity for any crops, or products derived therefrom, so thresholds that are consistent across all materials should be set and should not discriminate (e.g., thresholds for adventitious presence of biotechnology material should be the same as applied to thresholds for other unwanted material and vice versa). All measures should be proportionate, nondiscriminatory, and science based.

The issue of economic liability provisions that compensate growers for adventitious presence of biotechnology material is often raised and is hotly contested. Historically, legal systems have placed the burden of preventing adventitious presence of unwanted material in an agricultural crop on the grower of that crop. For example, seed breeders bear the legal burden of isolating certified seed crops from undesired pollination by a neighbor's crop of the same species. Breeders, not their neighbors, must use geographic isolation, physical barriers such as trees or hedgerows, and buffer zones to separate seed and non-seed crops. By extension, many biotechnology advocates have suggested that the onus of preventing unwanted cross pollination by biotechnology plants should fall on growers of any specialty crops, such as organic grains, fruits, and vegetables.

Many organic growers and others who wish to preserve the non-biotechnology identity of their crops counter that biotechnology and biotechnology crops are sufficiently different

from historical forms of 'contamination' and that the burden of preventing cross-pollination should fall on the growers of biotechnology varieties. Although, in the United States, organic products cannot be (legally) downgraded or the producer decertified by unintentional presence when all required measures and best practices are adhered to and no producer has been so impacted to date, there is a perception that these production systems have been negatively impacted. Indeed, as noted by Bradford (2011), among others, given that certain production systems, as noted organic, seek to prevent all the presence of GE products in organic commodities (although not required for certification), the implications on production agriculture in general that implementation of those extreme requirements would have is profound. In essence, in an effort to address the concerns that 'onerous measures carried out in an attempt to prevent contamination will similarly burden Plaintiffs Family Farmers,' as noted in the alfalfa lawsuit cited above, the onerous burden on conventional agricultural growers is discounted. In essence this means that an agricultural system that accounts for $<1\%$ of production agriculture in the United States can potentially dictate growing terms to the majority production system when their growing areas are contiguous. This is not only onerous but also disproportionate and potentially devastating for production agriculture in the United States.

Virtually all EU member states have transcribed EU Directive 2001/18 and implement EU regulations on traceability and labeling. Within the European Union, provision has been made for a *de minimis* threshold for the unavoidable presence of GMOs, but no actual threshold has been set. Therefore, the default state of the 0.9% on labeling and traceability is the one enforced. Indeed, there have been at least two occasions to date in which the presence of minute levels of transgenes in non-biotechnology crops has given rise to legal concerns. The transgene from Bayer Crop Sciences' unapproved LLRICE 604 were found in Clearfield 131 (CL131) rice seed in 2007, and the transgene from Mycogen's unapproved event '32' was discovered in maize in 2008. US regulatory agencies were able to move quickly and determine that these events did not prove any risk because they carried similar constructs to those already having achieved nonregulated status. The problem nevertheless rendered the 'contaminated' rice and corn unapproved for export, causing financial losses of millions of dollars for growers. In those cases, involving as yet unapproved biotechnology varieties, US courts determined that the developers did, in fact, have an obligation to ensure isolation from non-biotechnology and approved biotechnology crops.

For fully approved varieties, however, growers of specialty crops who have themselves chosen a more stringent standard than that established by the market for basic commodity products should not expect their neighbors to bear the special management costs of meeting that self-imposed standard. To do so would reverse fundamental freedom of economic activity and would establish a dangerous precedent. It would allow specialty operators to formulate unrealistic standards for biotechnology production, would impose impossibly high standards on neighbors, and would effectively impose a ban on the choice of other producers. Specialty crop growers usually are rewarded by higher prices and niche markets for taking such actions. Their neighbors enjoy no such advantage. Furthermore, because organic certification is process based, not content based, accidental cross-pollination of an organic crop by biotechnology plants does not, in fact, affect the organic status of the resulting food or feed.

If new regulations were adopted to address economic liability provisions for any negative economic consequences of adventitious presence of unwanted material, one might argue that the same principle should apply to all farmers regardless of their chosen production methods. On equity grounds, biotechnology growers should have equal access to compensation for adventitious presence of material from conventional or organic crops (such as fungal contamination) as conventional and organic producers have from biotechnology growers. All coexistence measures should be based on legal, practical, and scientific realities and not on commercial or niche marketing objectives.

According to Brookes and Barfoot (2008), fully approved biotechnology crops do generally coexist successfully with conventional and organic crops in North America (where, as noted, biotechnology crops account for the majority of acreage of important arable crops, like soybeans, cotton, and maize), Spain, and more recently the Czech Republic. The market has developed practical, proportionate, and workable coexistence measures without new regulations or indeed any government intervention. Where isolated instances of adventitious presence of biotechnology material have been found in conventional or organic crops, these have usually been caused by inadequate implementation of good coexistence practices (e.g., inefficient segregation of crops in storage and transport and nonuse of tested, certified seed).

Under civil liability (i.e., tort damages) and for intellectual property infringement (except for the unauthorized StarLink corn, which had received split approval only for animal consumption but was found in human food), there have been no lawsuits brought by any parties for adventitious presence. Every case brought by a seed company for infringement has involved a claim that the farmer charged with infringement was an intentional infringer (i.e., adventitious presence was not the issue). Moreover, to date each of these cases was upheld by the courts. Indeed, all except one notable exception in North America has conceded to this claim.

Therefore, the actual commercialization of biotechnology products may have little to do with technical limitations and more to do with external constraints, primarily the process of regulatory approval. The flagship of improved nutritional varieties, namely beta-carotene-enhanced rice (commonly referred to as golden rice), despite being under consideration since the late nineties and subject to a barrage of risk assessments has yet to receive approval. By incorporation of beta-carotene into rice cultivars and widespread distribution of this 'packaged technology in the seed,' it is estimated that it could prevent one to two million deaths each year. Ingo Potrykus, the developer, says an unreasonable amount of testing was required, without scientific justification. In a 2011 Nature article, he laid the blame solely at the door of the regulatory process that he considered excessive, stating "I therefore hold the regulation of genetic engineering responsible for the death and blindness of thousands of children and young mothers," (Potrykus, 2010).

Scientific, civic, and religious opinion leaders from all over the world have expressed support for the value of this

technology. Noted African scientist Florence Wambugu (1999) of Kenya stated that the great potential of biotechnology to increase agriculture in Africa lies in its 'packaged technology in the seed,' which ensures technology benefits without the need to change local cultural practices. Golden rice is a seminal example of this contention. Florence Wambugu observed that in the past, many foreign donors funded high-input projects, which had not been sustainable because they had failed to address social and economic issues, such as changes in cultural practice. In concurrence with this, Ismail Serageldin, former Chairman of the Consultative Group on International Agricultural Research (CGIAR), noted that a priori biotechnology could contribute to food security by helping to promote sustainable agriculture centered on smallholder farmers in developing countries. Harvard's developing economies expert Juma (2012) noted that Africa's precautionary approaches to biotechnology not only are misguided, but they also expose the continent to long-term political risks. He maintained that the issue is no longer a simplistic argument about becoming an importer of GM foods; it is about building up the requisite capacity to diversify the technological options needed for long-term agricultural adaptation. There are others that hold opposing positions, but their views, on the whole, are based on uninformed opinions unsupported by scientific data.

Future Directions

As agriculture must adapt to rapidly changing needs and growing conditions, we must become more effective at producing more or less with limited resources and only the tools of biotechnology will allow us to bypass physiological and environmental limitations to produce sufficient food, feed, fuels, and fiber on ever-diminishing arable land to meet ever-increasing demand. The challenges going forward are foremost technical as we strive to modify qualitative as opposed to quantitative traits and intricate metabolic pathways and networks as opposed to single genes; the scientific hurdles to achieve these aims are not trivial. However, with the tools now coming on line in the fields of genomics, proteomics, metabolomics, and bioinformatics, we have the potential to make major modifications to introgress desirable traits. For example, tools such as genome editing (using artificial nucleases such as Zn fingers, transcription activator-like effector nucleases, and clustered regularly interspaced short palindromic repeats), next-generation sequencing, RNAi, Tfs, minichromosomes, non-integrating vectors, combinatorial transformation, epigenetic modification, network engineering, synthetic biology, and systems biology will allow us to apply both reductive and holistic approaches to identify, modify, introgress, and subsequently simultaneously study the expression and interaction of transgenes on tens of thousands of endogenous genes in elite germplasm backgrounds. With rapidly emerging technologies, the increase in our understanding of, and ability to, manipulate plant metabolism during the coming decades should place plant researchers in the position of being able to modify crop traits to respond to the diverse needs from minimizing environmental impact to optimizing productivity and quality output.

Nontechnical limitations to adoption of this technology include intellectual property restrictions that may limit translation of public research if not managed judiciously; second, liability concerns over use, abuse, or misuse of constructs; third, prohibitive and asymmetric biosafety regimes; and finally public acceptance. The latter two in many ways are the most insidious of limitations as they have little basis in rational process and thus are difficult to redress effectively – the last in particular is often predicated on how much of the former is perceived to be of concern, and how positions are presented by the opposing factions. It is often easier to appeal to emotion and sell fear than it is to present reasoned and judicious scientific rational for basing risk analysis. Indeed, the actual commercialization of biotechnology products may have little to do with technical limitations and more to do with these external constraints, primarily the process of regulatory approval. As a noted case in point, 'golden' rice is only now at the point of finally being approved for commercialization, (Potrykus, 2010), where the blame has been laid on the regulatory process for the delay in approval. As noted by Juma (2012), biotechnology is not simply a matter of rhetorical debate guided by short-term interests; it is central to how countries define their place in the global knowledge ecology.

Given that resources are finite, we must be pragmatic in our assessment of agricultural methodologies and insure that we deploy approaches that make the most sense in any given circumstance. Genuine sustainability can only be attained by promoting the development of resource-enhancing technologies. The only sure way to protect the planet's resources is not to settle into the complacency of maintaining the status quo but to engage in continual, constructive change based on scientific knowledge. If we are to be accountable to posterity, it is not just our choice but our duty to promote and apply responsible science and technology in all endeavors.

Biotechnology: Herbicide-Resistant Crops

SO Duke, USDA, ARS, Oxford, MS, USA

Published by Elsevier Inc.

Glossary

Auxinic herbicide A herbicide such as 2,4-dichlorophenoxyacetic acid that acts as a synthetic form of the plant hormone indoleacetic acid (auxin).
Deregulation The approval of a transgenic crop by regulatory agencies for its commercialization.
Dicotyledonous A flowering plant with two cotyledons in the seed.
Gene stacking The process of inserting more than one functional transgene into an organism by genetic engineering.
Monocotyledonous A flowering plant with a single cotyledon in the seed, for example, grasses, lilies, and orchids.
Photosystem II The first protein complex of the light-dependent processes of photosynthesis in which water is split.
Shikimate pathway The biochemical pathway that leads to the synthesis of the aromatic amino acids phenylalanine, tryptophan, and tyrosine and their derivatives.
Transgene A gene that has been inserted into the genome of an organism by genetic engineering.

Introduction

In the developed world, weeds have been managed primarily with herbicides since the middle of the past century. The first highly successful herbicide – 2,4-dichlorophenoxyacetic acid (2,4-D) – killed most dicotyledonous weeds, but at the same time it did not injure monocotyledonous crops or turf. Subsequently, companies involved in herbicide discovery screened for selective compounds that kill important weeds without significantly injuring crops. Such products usually killed only a fraction of the important weeds in a crop, so that another selective herbicide with a different weed species spectrum also had to be used in the crop if the farmer was to rely on herbicides for weed management. Minor crop injury commonly occurred with selective herbicides, but farmers were willing to accept this risk in return for good weed management, as weeds can devastate a crop if not controlled. Nonselective herbicides that kill all plants, like paraquat or glyphosate, were usually used with crops only before planting or after harvesting.

Except for auxinic herbicides such as 2,4-D and grass-killing herbicides inhibiting acetyl-CoA carboxylase (ACCase), the mechanism of crop selectivity did not involve resistance at the molecular target site of the herbicide. Most selective herbicides did little harm to the crop because the crop metabolically degraded the active ingredient much more rapidly than the weed. For example, triazine herbicides are quickly degraded by maize (Esser *et al.*, 1975), the crop of their primary use, even though these herbicides are active at the D-1 site of photosystem II (PSII) of all plants. For most selective herbicides, phytotoxicity to a crop is variable, depending on factors that might influence metabolic degradation of the herbicide, such as climatic conditions. A concern of herbicide manufacturers was that the 'selective' herbicide might cause unacceptable problems in cultivars for which it had not been tested. Use of compounds that induce increased metabolism of the herbicide by the crop (herbicide safeners) to provide protection has been one approach to protect the crop from unacceptable herbicide damage (Rosinger *et al.*, 2012). This approach further complicates weed management and adds another chemical to the environment.

Thus, finding a genetic approach to manipulate the crop in order to make it resistant to the herbicide was an attractive alternative to manipulation of the chemical or the crop's response to a herbicide with a safener. Attempts were made to find crop cultivars with resistance to existing commercial herbicides. For example, the Tracy-M cultivar of soybeans was resistant to metribuzin, an inhibitor of PSII, to which other varieties of soybean were significantly more sensitive (Barrentine *et al.*, 1982; Klein and He, 1992), thus indicating that germplasm for herbicide resistance exists in some crops. This approach was not successful in expanding the use of any herbicide with any crop. Another approach was to introgress evolved resistance genes from weedy relatives into crops. The only success with this approach was the use of the evolved triazine-resistant bird's turnip rape (*Brassica campestris*) germplasm to produce triazine-resistant canola (Hall *et al.*, 1996). Commercial triazine-resistant canola was produced with this method and was introduced into the market in 1984, gaining a small amount of market share in Canada first and much later in Australia. However, the resistance gene produces a modified D1 protein that, although resistant to triazines, is not quite as efficient in PSII, resulting in reduced yield under some environmental conditions (Hall *et al.*, 1996).

The real success in altering crops to resist herbicides has come from gene selection in tissue culture and transgene technology. The former method has produced crops resistant to two major classes of herbicides. They are the sulfonylurea and imidazolinone inhibitors of acetolactate synthase (ALS) and the cyclohexanedione and aryloxyphenoxypropionate (AOPP) inhibitors of ACCase. These nontransgenic herbicide-resistant (HR) crops will be discussed, but most of this article will deal with transgenic HR crops, particularly glyphosate-resistant (GR) crops, as these crops have had the most impact on weed management and agriculture. Several books and reviews are available that deal with the topic of transgenic HR crops in general (e.g., CaJacob *et al.*, 2004; Duke, 1996; Duke and Cerdeira, 2005, 2010; Martino-Catt *et al.*, 2012; Nandula,

 doi:10.1016/B978-0-444-52512-3.00218-7

2010) and on GR crops in particular (e.g., Dill *et al.*, 2008; Green, 2009). Special issues of the journal *Pest Management Science* have dealt with HR crops from biotechnology in March 2005 and with GR weeds and crops in April 2008. This article will try to cover the more important information from these sources, while updating the information in this rapidly moving field of science and agriculture.

Nontransgenic Herbicide-Resistant Crops

HR crops can be generated for some herbicides by selecting for target site mutations in plant populations or tissue culture or by mutation breeding. Green and Castle (2010) and Green and Owen (2011) have reviewed this topic. This approach to produce HR crops has worked for herbicides with relatively plastic molecular targets to which resistance evolves easily, such ALS and ACCase inhibitors. This plasticity is proven by the fact that there are 129 and 42 weed species, respectively, that have evolved resistance to herbicides that target these two enzymatic sites, almost exclusively due to target site mutations (Heap, 2013). Crops made resistant to grass-killing ACCase-inhibitor herbicides, such as aryloxyphenoxypropionates and cyclohexanediones, by selection for resistance in tissue culture have not gained large market shares, although there were substantial efforts to develop such crops (Somers, 1996). These crops were all resistant by means of a HR ACCase. Maize made resistant to the cyclohexanedione herbicide sethoxydim was commercialized in 1996 (Green and Owen, 2011). Adoption of sethoxydim-resistant maize never rose to more than 1%, and it is no longer available (Martino-Catt *et al.*, 2012). The reason(s) for the failure of these nontransgenic crops to gain wider market share is unclear. This question is intriguing in that transgenic ACCase-inhibitor HR crops requiring much more regulatory data for approval are now being developed (see below).

Crops have been made resistant to sulfonylurea herbicides by selection for ALS mutations (Saari and Mauvais, 1996). Nontransgenic sulfonylurea-resistant soybeans (STS™) were commercialized in 1993, 3 years before the first transgenic HR soybeans. Before 2005, this product accounted for 2–4% of the soybean market, but its market share declined thereafter (Martino-Catt *et al.*, 2012), largely due the success of GR crops. The number of active ingredients used on at least 10% of the US soybean area dropped from 11 in 1995 to only 1 (glyphosate) in 2002 (Green and Owen, 2011).

Crops made resistant by selection of ALS mutations to impart resistance to imidazolinone herbicides, another chemical class of ALS inhibitors, have been relatively successful. Imidazolinone-resistant rice, wheat, sunflower, lentils, canola, and maize are commercially available. The first of these crops, maize, was launched in 1992. Single-codon mutation-based ALS resistance was selected in mutagenized seed (rice and wheat) and microspores (canola), as well as simple selection in tissue culture (maize) or in the field (sunflower) (Shaner *et al.*, 1996; Tan *et al.*, 2005). In the case of wheat, which has three genomes, each apparently with its own ALS, two resistant ALS genes provide optimal resistance, especially in spring wheat (Tan *et al.*, 2005). These crops have been the most successful of the nontransgenic HR crops, perhaps in part because no other HR rice, wheat, sunflower, or lentils are available. Where GR maize and canola are available, imidazolinone-resistant crops have not been very competitive, primarily because of the superior characteristics of glyphosate compared with any imidazolinone herbicide (Duke and Powles, 2008). As GR maize was adopted, the market share of imidazolinone-resistant maize decreased from a maximum of approximately 5% during 1999–2002 to less than 1% in 2009 (Martino-Catt *et al.*, 2012). Imidazolinone-resistant canola was introduced in 1995 and rose to approximately 10–20% adoption rates, depending on the year, from 1997 to 2004 (Martino-Catt *et al.*, 2012).

Clearly, imidazolinone-resistant crops have been the most successful nontransgenic HR crops. As mentioned earlier, evolution of weeds resistant to ALS-inhibiting herbicides occurs relatively quickly. Thus, one might expect a problem with imidazolinone-resistant weeds in these crops after only a few years. Stewardship programs have been instituted to avoid or delay this problem.

Because the mutated genes only generate isoforms of enzymes that are already in the crop, and there is no insertion of new DNA into the genome, unintended consequences of the mutation are considered highly unlikely, and regulatory approval of the genetics of such crops is not needed. One of the weed management advantages of imidazolinone-resistant crops is that closely related weed species, such as red rice (a feral *Oryza sativa*) in rice, can be controlled by a herbicide that was previously active on both the crop and weed. But, gene flow from the crop to the close relative is much more likely in the presence of the selection pressure of the herbicide. In fact, imidazolinone-resistant red rice has appeared in imidazolinone-resistant rice in several countries (Kaloumenos *et al.*, 2013; Scarabel *et al.*, 2012; Valverde, 2007). The majority of appearance of resistant red rice is apparently due to gene flow, but some of it is due to evolved resistance (Dos Reis Goulart *et al.*, 2012; Rajguru *et al.*, 2005; Shivrain *et al.*, 2007). Although the outcrossing rate is low, spraying the selected herbicide enforces introgression of the resistance gene into the feral population of red rice. Strategies to mitigate gene flow in rice have been devised and called for in order to retain the utility of imidazolinone-resistant rice (Gressel and Valverde, 2009). There has also been concern about flow of the resistance gene from imidazolinone-resistant wheat to jointed goatgrass (*Aegilops cylindrica*), as the two species can interbreed under field conditions (Seefeldt *et al.*, 1998; Gaines *et al.*, 2008).

Many weed species have evolved resistance to ALS-inhibitor herbicides (Heap, 2013), and there is sometimes cross-resistance to imidazolinones for resistant weeds selected by nonimidazolinone ALS-inhibitor herbicides (e.g., Hashem and Dhammu, 2002). Widespread use of all types of ALS-inhibitor herbicides and the ease with which weeds evolve target-site resistance to all ALS inhibitors make resistance management problematic.

Imidazolinone-resistant crops can be used to control parasitic weeds, in that imidazolinones translocate to metabolic sinks, such as infecting parasitic weeds (e.g., *Striga* spp.). Thus, seeds of resistant maize can be coated with herbicide in order to provide *Striga* control (De Groote *et al.*, 2007; Kanampiu *et al.*, 2009). This method can provide season-long

control of these highly destructive weeds (Ransom *et al.*, 2012). However, the rapid evolution of resistance to ALS inhibitors indicates that any weed that survives this treatment should be destroyed before they produce seed.

Some imidazolinones have long soil residual properties, disallowing the planting of a nonresistant crop the next year, for example, planting barley after imidazolinone-resistant wheat. To deal with this problem, the development of imidazolinone-resistant barley by mutation breeding was proposed (Lee *et al.*, 2011). In this case, imidazolinone herbicides would not be used with barley.

Transgenic Herbicide-Resistant Crops

Bromoxynil-Resistant Crops

One of the first commercially available HR transgenic crops, in 1995, was bromoxynil-resistant cotton (**Table 1**). It was followed, in 2000, with bromoxynil-resistant canola. Bromoxynil (3,5-dibromo-4-hydroxybenzonitrile) is a selective PSII-inhibitor herbicide (Fedtke and Duke, 2005) that kills only certain weeds at recommended doses. It also kills dicotyledonous crops at these doses and can be used on some grass crops, such as maize, that are much less sensitive. Thus, making crops resistant to bromoxynil gave farmers another tool for managing certain weed species in sensitive crops.

Only three weed species have evolved resistance to bromoxynil (Heap, 2013). The first case was common groundsel (*Senecio vulgaris*), in 1995 in Oregon, in a peppermint field in which bromoxynil was used for weed management (Park and Mallory-Smith, 2006). The other cases were for maize in Canada in 2004 (smooth pigweed, *Amaranthus hybridus*) and 2005 (redroot pigweed, *Amaranthus retroflexus*) (Heap, 2013). Thus, the selection pressure in bromoxynil-resistant cotton and canola was apparently too weak in geographic scope and duration for bromoxynil-resistant weeds to evolve in these crops.

The transgene for bromoxynil resistance was derived from an isolate of the soil microbe *Klebsiella ozaenae* collected in bromoxynil-contaminated soil (reviewed by Stalker *et al.*, 1996). This isolate could use bromoxynil as a sole source of nitrogen. This gene encodes a nitrilase that converts bromoxynil into a nonphytotoxic derivative, 3,5-dibromo-4-methoxybenzoic acid. The enzyme has substrate specificity for bromoxynil over other nitrile compounds (McBride *et al.*, 1986). In initial studies, the gene provided crops a 10-fold level of resistance to the herbicide (Stalker *et al.*, 1988). In the field, 20-fold field rates caused no sustained damage to bromoxynil-resistant cotton (Stalker *et al.*, 1996).

The market share for these two GR crops was small. This may be partly because the weed species spectrum killed by bromoxynil was limited, giving it little advantage over other nonselective herbicides used in cotton and canola. Also, GR crops that were introduced in canola in 1996 and cotton in 1997 (**Table 1**) had great advantages over bromoxynil-resistant crops (discussed below), although there were a few weed situations in which a farmer might find the bromoxynil-resistant crop cost effective. In the only published assessment comparing a bromoxynil-resistant crop with a GR crop, Clewis and Wilcut (2007) estimated a higher net economic return in GR cotton than in bromoxynil-resistant cotton. Both bromoxynil-resistant crops were discontinued for economic reasons (cotton in 2004 and canola in 2001). Interestingly, volunteer bromoxynil-resistant canola was collected in Canadian fields as late as in 2007, 6 years after it was discontinued (Beckie and Warwick, 2010). Another phenomenon that occurred with bromoxynil-resistant canola was unintentional gene stacking of the bromoxynil resistance gene with genes from other HR canola cultivars through gene flow between glufosinate and GR canola varieties (Beckie *et al.*, 2004). The abandonment of the bromoxynil-resistant crops is perhaps unfortunate, as this option would have been useful in creating the weed management diversity needed to mitigate or slow the evolution of glyphosate resistance, especially because most of the weeds that have evolved resistance to glyphosate in North America are broadleaf species that are sensitive to bromoxynil.

Table 1 Transgenic herbicide-resistant crops that have been or are now available for planting in the US

Herbicide	*Crop*	*Year of introduction*
Bromoxynil[a]	Cotton	1995
	Canola	2000
Glufosinate	Canola	1995
	Maize	1997
	Cotton	2004
	Soybean	2011
Glyphosate	Soybean	1996
	Canola	1996
	Cotton	1997
	Maize	1998
	Sugar beet	2008
	Alfalfa[b]	2005

[a]All bromoxynil resistant crops have been withdrawn from the market.
[b]Removed from market by court order in 2007 but returned to the market by a US Supreme Court ruling and after further USDA/Animal and Plant Health Inspection Service examination in 2011.

Glufosinate-Resistant Crops

Glufosinate-resistant crops also were first introduced for commercial production in 1995 (**Table 1**). Glufosinate (DL-2-amino-4-(hydroxy(methyl)phosphonoyl)butanoic acid) is the chemically synthesized racemic mixture of the D and L stereoisomers of the natural compound L-phosphinothricin, which is produced by several taxa of *Streptomyces* (Copping and Duke, 2007; Lydon and Duke, 1999). Only the natural form, the L-isomer, is herbicidally active. Glufosinate is a nonselective herbicide that kills many weed species, but not as many as glyphosate (Feng *et al.*, 2010).

Glufosinate kills plants by inhibition of glutamine synthetase (GS) (reviewed by Lydon and Duke, 1999). Inhibition of chloroplast GS by glufosinate is essentially irreversible and causes rapid accumulation of one of its substrates, ammonia, which is highly toxic (Lydon and Duke, 1999; Sellers *et al.*, 2004). Loss of glutamine, and subsequently glutamate, leads to inhibition of photorespiration due to missing amino acid donors (Wild and Wendler, 1993). Inhibition of photorespiration in sunlight results in oxidative damage to the

chloroplast. Glufosinate is a fairly fast-acting herbicide and is more like bromoxynil than glyphosate. Like glyphosate, glufosinate is a nonselective, foliar-applied herbicide; however, glufosinate does not have all of the desirable attributes of glyphosate (see below). For example, it translocates relatively poorly in some species (Everman *et al.*, 2009), although this is not true for all species (e.g., Grangeot *et al.*, 2006). The relatively fast action of glufosinate may reduce its movement from strongly affected sites of herbicide deposition after spraying.

Phosphinothricin-producing *Streptomyces* spp. also have an enzyme that detoxifies L-phosphinothricin by acylating it. This enzyme is encoded by the *bar* gene. *Bar* is the abbreviation of bialaphos resistance. Bialaphos is a GS-inactive tripeptide produced by the same microbe. It is degraded by plants to form L-phosphinothricin. The *bar* gene is used in glufosinate-resistant cotton. A very similar gene (the *pat* gene; phosphinothricin acyl transferase) from a different *Streptomyces* species will also generate glufosinate-resistant plants (Wehrmann *et al.*, 1996). It is used in glufosinate-resistant maize and soybean. Both genes have been used extensively as selectable markers for selection of transformants (Jones and Sparks, 2009). Use of the *bar* and *pat* genes in commercial glufosinate-resistant crops produces a very high level of resistance all the way to flowering and beyond (Áy *et al.*, 2012; Thomas *et al.*, 2004). A concentration of 64 times the lethal dose for nonresistant wheat was reported to have no effect on yield of glufosinate-resistant wheat transformed with the *bar* gene (Áy *et al.*, 2012). *Pat* genes from *Nocardia* sp. have also been used as transgenes to experimentally produce glufosinate-resistant crops (Kita *et al.*, 2009; Yun *et al.*, 2009).

Four glufosinate-resistant crops (canola, maize, cotton, and soybean) are available in the US (**Table 1**). Glufosinate-resistant rice was deregulated (approved for sale) but never commercialized, perhaps partly because of the potential problem of gene flow to weedy rice and nontransgenic rice (Oard *et al.*, 2000; Olofsdotter *et al.*, 2000; Sanchez-Olguin *et al.*, 2009; Song *et al.*, 2011). The adoption of glufosinate-resistant crops has been only a small fraction of the HR crop market, primarily because glyphosate is a more effective herbicide than glufosinate on many weed species. However, the growing evolution of GR weeds is increasing the adoption of glufosinate-resistant crops. Glufosinate is effective on some GR weeds such as palmer amaranth (*Amaranthus palmeri*) (Hoffner *et al.*, 2012), perhaps the most problematic GR weed (see Section Glyphosate-Resistant Crops). Resistance to glufosinate has not yet evolved in glufosinate-resistant crops, but it has evolved in *Eleusine indica* and *Lolium multiflorum* in orchards where glufosinate was used year after year (Avila-Garcia and Mallory-Smith, 2011; Heap, 2013). The mechanism of evolved resistance in one glufosinate-resistant Italian ryegrass (*Lolium perenne* L. ssp. *multiflorum*) biotype is a one-codon change in chloroplast GS, making it less sensitive to glufosinate (Avila-Garcia *et al.*, 2012). Other biotypes apparently have a different mode of resistance (Avila-Garcia and Mallory-Smith, 2011). Again, the absence of evolved resistance to glufosinate in glufosinate-resistant crops is probably due to low selection pressure, as defined by limited use of these crops in space and time.

Glufosinate-resistant canola can outcross with other canola varieties, as well as weedy relatives. In Canada, both glufosinate and GR canola (both transgenic) and imidazolinone-resistant canola (nontransgenic) are grown from commercial seeds that have only one of these resistances. Yet, all combinations of these resistances have been found in individual volunteer canola plants, both outside and within canola fields (Knispel *et al.*, 2008; Schafer *et al.*, 2012b). Gene flow can also occur between glufosinate-resistant canola and weedy relatives (Song *et al.*, 2010). Fully introgressed *bar* genes into weeds have not been documented. This scenario requires that the F1 and subsequent backcrosses be fit in the absence of glufosinate or that each cross be subjected to glufosinate. F1 hybrids of some canola/weedy relative combinations are not very fit (e.g., Scheffler and Dale, 1994), yet there are reports of introgression of the *cp4* glyphosate-resistance gene from commercial canola into a weed relative *Brassica rapa* (Warwick *et al.*, 2008). The gene was persistent in the population more than a 6-year period, despite the fitness cost of hybridization and absence of glyphosate use (with the exception of one possible exposure). Nevertheless, gene flow from HR canola to weedy relatives has not created a major weed problem.

There are potential benefits of glufosinate-resistant crops in addition to weed management. Glufosinate is fungitoxic (Liu *et al.*, 1998) and bactericidal (Pline *et al.*, 2001) and provides some level of protection from plant diseases in glufosinate-resistant crops. For example, glufosinate reduced the severity of rice blast and brown leaf spot in glufosinate-resistant rice (Ahn, 2008). The herbicide also provides some degree of protection to glufosinate-resistant soybean from *Pseudomonas syringae* pv. *glycinea* at field rates (Pline *et al.*, 2001). Glufosinate also reduces fungal diseases in glufosinate-resistant bentgrass (*Agrostis* spp.) (Liu *et al.*, 1998; Wang *et al.*, 2003). There may be similar benefits of glyphosate in GR crops with some plant pathogens.

As mentioned earlier, the *bar* gene is used extensively as a selectable marker in transgenic plant production. Therefore, any crop could be made glufosinate resistant (e.g., peppermint – Li *et al.*, 2001 and wheat – Áy *et al.*, 2012). However, the current costs in gaining approval for commercialization of transgenic crops, as well as variety development costs, preclude the introduction of many more glufosinate-resistant crop species. At least in the foreseeable future, new glufosinate-resistant crops will more likely be existing glufosinate-resistant crops (canola, cotton, maize, and soybean) with genes for resistance to other herbicides stacked with them.

Glyphosate-Resistant Crops

Glyphosate: The herbicide

Glyphosate (*N*-(phosphonomethyl)glycine) is the most successful herbicide in history in terms of market share and customer satisfaction (Duke and Powles, 2008). Before GR crops were available, glyphosate was a successful herbicide, but its use grew substantially due to its use in glyphosate-resistant (GR) crops. Because glyphosate is a very good nonselective herbicide, it could only be used with agronomic crops before planting, after crop maturity or harvest, or with devices that did not allow the herbicide to reach the foliage of the crop (e.g., shielded sprayers and rope-wick applicators). It was also heavily used in perennial horticultural crops (e.g., grapes and

tree crops) when foliage had not appeared in the crop or with ground spraying below the crop foliage. It was also used in many noncrop situations. It is considered a very safe herbicide, as its acute toxicity is lower than that of aspirin or NaCl. The vast majority of toxicological studies have found glyphosate to be very safe to mammals from both an acute and a chronic standpoint (Mink *et al.*, 2012; Williams *et al.*, 2000, 2012).

Glyphosate is the only herbicide that kills plants by inhibition of the enzyme 5-enolpyruvylshikimate-3-phosphate synthase (EPSPS). The fact that there is no secondary mode of action at doses of glyphosate used in the field is clear from the finding that plants with a transgene that encodes a resistant form of EPSPS are approximately 50-fold more resistant to glyphosate than untransformed plants (Nandula *et al.*, 2007). EPSPS is a critical enzyme of the shikimate pathway, from which the three aromatic amino acids (phenylalanine, tyrosine, and tryptophan) are derived. The sequence of events causing death of the plant after inhibition of EPSPS is not entirely clear. The most rapid effect is the accumulation of shikimate acid and benzoates in affected plant tissues (Amrhein *et al.*, 1980; Lydon and Duke, 1988). Inhibition of carbon fixation can also be very rapid in some species (e.g., Servaites *et al.*, 1987), apparently due to the loss of carbon intermediates, which, in turn, is caused by the loss of regulation of carbon flow into the shikimate pathway (Siehl, 1997). Certainly, levels of aromatic amino acid are reduced, so is the synthesis of auxin from tryptophan and many secondary products that are derived from aromatic amino acids. Thus, many physiological functions are compromised by this herbicide. Glyphosate is perhaps the most slow-acting herbicide that is sold. Its slow action allows it to translocate throughout the plant, like sucrose, to metabolic sinks (Gougler and Geiger, 1981), such as meristems, where it concentrates. Thus, all growing points of the plant are killed, eliminating regrowth. This makes it very effective on perennial weeds with subterranean rhizomes or stolons that make these species less vulnerable to other herbicides.

Transgenes for glyphosate-resistant crops

Three transgenes for glyphosate resistance have been used in commercially available GR crops. The predominantly used gene has been the *cp4* gene from *Agrobacterium* sp., which encodes a GR EPSPS (Green, 2009). In some maize varieties, a maize EPSPS gene (*TIPS-EPSPS*) modified by site-directed mutagenesis of two codons was used for G21 varieties (Dill, 2005; Feng *et al.*, 2010; Pollegioni *et al.*, 2011). TIPS-EPSPS is kinetically inferior to CP4 EPSPS in the presence of glyphosate. This gene was used only for the first generation of GR maize and was replaced by the *cp4* transgene in the second generation of GR maize (Feng *et al.*, 2012). Until now, all GR canola has contained both *cp4* and a gene (*goxv247*) from the soil bacterium *Ochrobactrum anthropi*, which encodes glyphosate oxidoreductase (GOX), an enzyme that degrades glyphosate to glyoxylate and aminomethylphosphonic acid (AMPA) (reviewed by Duke, 2011a). The microbial GOX gene was modified by mutagenesis and selection for variants with better enzymatic efficiency, as well as some codon modification for better expression in plants (Pollegioni *et al.*, 2011). The GOX transgene alone does not provide sufficient resistance for commercialization (Feng *et al.*, 2012), but why *cp4* alone was not sufficient for commercial resistance in canola has not been divulged. Second generation GR canola with a different promoter for *cp4* will not include a gene for GOX. An uncharacterized plant GOX can occur in some crops and weeds, but not in sufficient amounts to provide natural resistance to glyphosate (Duke, 2011a; Reddy *et al.*, 2008). Some soil microbes contain C-P lyase that will degrade glyphosate to sarcosine and inorganic phosphate (e.g., some *Arthrobacter* spp., *Rhizobium* spp., and *Pseudomonas* spp.) (Kishore and Jacob, 1987; Liu *et al.*, 1991; Dick and Quinn, 1995). However, there are no reports of using the gene for this enzyme to render plants resistant to glyphosate.

Overexpression of glyphosate-sensitive EPSPS was proposed early during the quest for GR crops, but greater than 20-fold-increased expression did not produce plants that were completely resistant to field rates of glyphosate (Shah *et al.*, 1986). This is interesting because biotypes of Palmer amaranth (*A. palmeri*) have evolved up to 160-fold more copies of the natural EPSPS gene by gene amplification, resulting in more EPSPS protein and extractable EPSPS activity, and are highly resistant to glyphosate (Gaines *et al.*, 2010). These resistant biotypes do not seem to pay any fitness penalty and may even have an advantage under drought stress (Chandi *et al.*, 2013). If crops could be manipulated this way, GR crops without transgenes might be possible.

Other transgenes encoding GR EPSPS have been proposed for generating GR crops. For example, a gene ($aroA_{1398}$) for GR EPSPS was selected with glyphosate in an unidentified soil microbe and used as a transgene in maize, producing plants that were highly resistant to glyphosate (Vande Berg *et al.*, 2008). Five rounds of gene shuffling and screening were used to produce a GR EPSPS from apple with two amino acid changes that provided a high level of resistance (Tian *et al.*, 2013). This transgene imparted glyphosate resistance to rice, although the level of resistance was unclear. An artificial transgene was produced by gene shuffling of a gene from *Bacillus licheniformis*, which had a weak ability to acetylate glyphosate (Castle *et al.*, 2004; Siehl *et al.*, 2005). After 11 iterations of gene shuffling, the final version of the glyphosate acetyl transferase (GAT) had enzymatic activity roughly four orders of magnitude greater than the native enzyme. This transgene provides good levels of resistance to glyphosate in crops (Green *et al.*, 2008, 2009). A fungal glyphosate decarboxylase confers resistance to glyphosate (Hammer *et al.*, 2007), but there is no indication at this time of it being commercialized.

Adoption of glyphosate-resistant crops

Commercial GR crops have been rapidly adopted. Crops with transgenic *Bt* toxin for insect resistance, glyphosate resistance, or a combination of these two traits represent almost 100% of all transgenic crops grown on 160 million ha of land worldwide, as of 2012 (James, 2012). GR crops with (in maize and cotton) or without *Bt* toxin represent more than 80% of all transgenic crops sold worldwide, and their market share continues to grow globally (Duke, 2011b). The GR trait is by far the most predominant transgenic trait worldwide. This technology has had more influence on weed management than any other since the advent of synthetic herbicides.

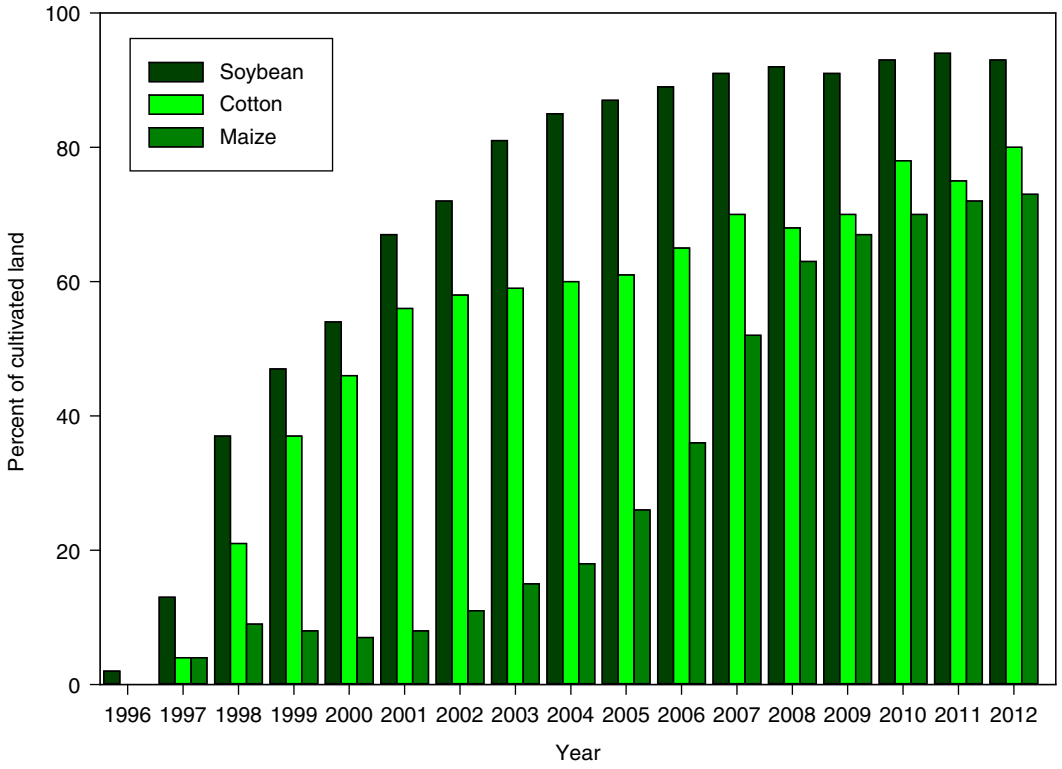

Figure 1 Adoption of GR crops in the US by year. Data from http://www.ers.usda.gov/data-products/adoption-of-genetically-engineered-crops-in-the-us.aspx

In the US, adoption of GR soybeans rose to approximately 90% within 10 years after its introduction (**Figure 1**). Adoption of GR soybeans was even more rapid in Argentina, reaching 90% within 4 years (Penna and Lema, 2003), and adoption in other parts of South America has also been very rapid (Cerdeira *et al.*, 2011). Adoption of GR cotton was also rapid, reaching almost 70% within 10 years and now at approximately 80%. The GR trait was slower to be used in maize, but after a lag period of approximately 5 years, its adoption rose rapidly to reach that of cotton (**Figure 1**). The slower adoption of maize was in part related to trade restrictions on transgenic maize (Martino-Catt *et al.*, 2012) and in part due to inexpensive and adequate weed management with existing selective herbicides. Adoption of GR sugar beet in the US was almost 100% after only 2 years of its commercial release. Canola is the only GR crop in which adoption has not been very rapid. Within 4 years of introduction of GR canola to North America (95% of the canola in North America is in Canada), adoption leveled off at approximately 40% and has remained at that level (Martino-Catt *et al.*, 2012). In 2009, most of the rest of the canola market was glufosinate resistant, with a few percent being resistant to imidazolinone through nontransgene technology (see Section Nontransgenic Herbicide-Resistant Crops).

Adoption of GR crops also led to reduced use of other herbicides in these crops. For example, glyphosate replaced almost all of the herbicides used in soybeans in the US by 2006 (**Figure 2**). This loss of market share for other herbicides in major agronomic crops led to devaluation of the herbicide market, leading to reduced prices of herbicides competing with glyphosate (Nelson and Bullock, 2003) and reduced herbicide discovery efforts by major agrochemical companies (Duke, 2012). These economic impacts were exacerbated by the loss of patent protection on glyphosate in 2000 and the consequent dramatic decreases in the price of glyphosate.

Perhaps the most obvious driving force for this rapid adoption has been economics. For example, since its introduction, GR soybeans have boosted farm income globally by $32.2 billion (Brookes and Barfoot, 2013). In addition to economic drivers, surveys of the US farmers who grow GR soybeans, maize, and cotton found that other important factors promoting adoption were perceived reduced adverse effects on family health, better weed management efficacy, improved safety to the crop, consistency, and good yields (Hurley *et al.*, 2009). All of these factors were rated above cost benefits among factors influencing herbicide choices. Despite the claims by some that the transgene, glyphosate, or both adversely affect yields of GR crops (e.g., Johal and Huber, 2009; Zobiole *et al.*, 2010c; 2011b), trends in yield increases in GR cotton, soybean, and maize after they were introduced have remained the same as before their introduction (**Figure 3**). Analysis of the available literature on yield of HR crops led Darmency (2013) to the conclusion that there are no significant effects of the transgenes for GR or any other HR crops on yield. The flexibility and time-saving aspects of GR crops have allowed small farmers to increase household incomes by having time for off-farm employment (Fernandez-Cornejo *et al.*, 2005, 2007; Gardner *et al.*,

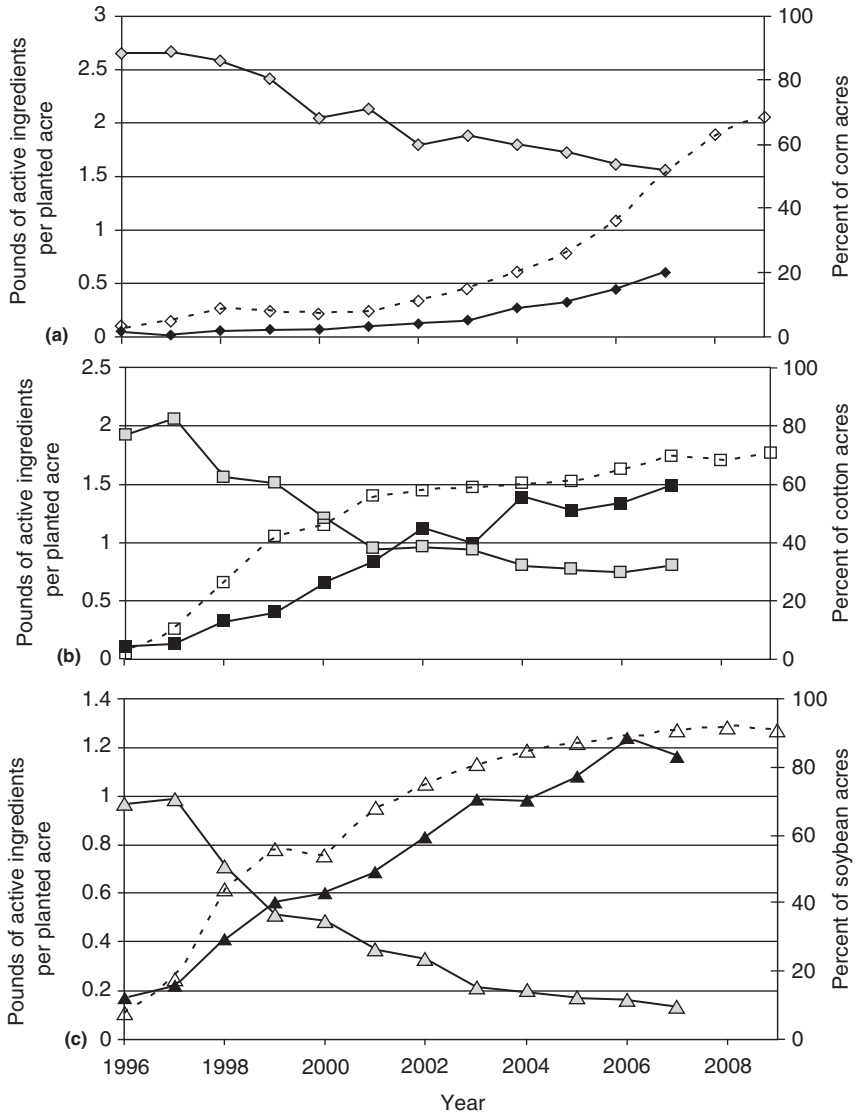

Figure 2 Quantity of glyphosate (dark symbols) and all other herbicides (gray symbols) used on the US crop areas (A, maize; B, cotton; and C, soybean). Open symbols are percent adoption of GR crop. Reproduced with permission of the National Academies Press from Ervin, D.E., Carrière, Y., Cox, W.J., *et al.*, 2010. The Impact of Genetically Engineered Crops on Farm Sustainability in the United States. Washington, DC: National Research Council, The National Academies Press, 250 pp.

2009). Thus, this technology has been as or more beneficial to farmers of small holdings as or than to big agribusiness operations.

How much additional growth will occur in the adoption of GR technology is dependent on several factors. GR soybeans are already 81% of the global market and a substantial portion of the global cotton market (James, 2012), so there is not much room for growth in these crops. However, GR crops represent a much lower fraction of the global area planted to maize and canola crops. There is no GR rice or wheat. GR wheat was almost introduced in North America but was not commercialized largely because of concern about foreign market acceptance. Rapid increases in the evolution of GR weeds and weed shifts to naturally resistant weed species is causing farmers to diversify weed management tools. One approach to diversification is to not use glyphosate in the same field year after year. Also, this impending diversification is not reflected in the data from **Figure 1**, but it may influence GR crop adoption in the future.

Environmental impact of glyphosate-resistant crops

HR crops in general and GR crops in particular have received high-profile bad press from the time before their introduction (e.g., Goldberg *et al.*, 1990) to the present (e.g., see Benbrook, 2012; Mortensen *et al.*, 2012). However, unknown to most of the public, the environment has generally benefited from the adoption of GR crops (Bonny, 2011; Duke and Cerdeira, 2005; Cerdeira and Duke, 2006; Green, 2012; Shiptalo *et al.*, 2008). A study of all available data by a US National Research Council committee concluded that HR crops (which during the period of the studies were more than 95% GR crops) generally have fewer adverse effects on the environment than

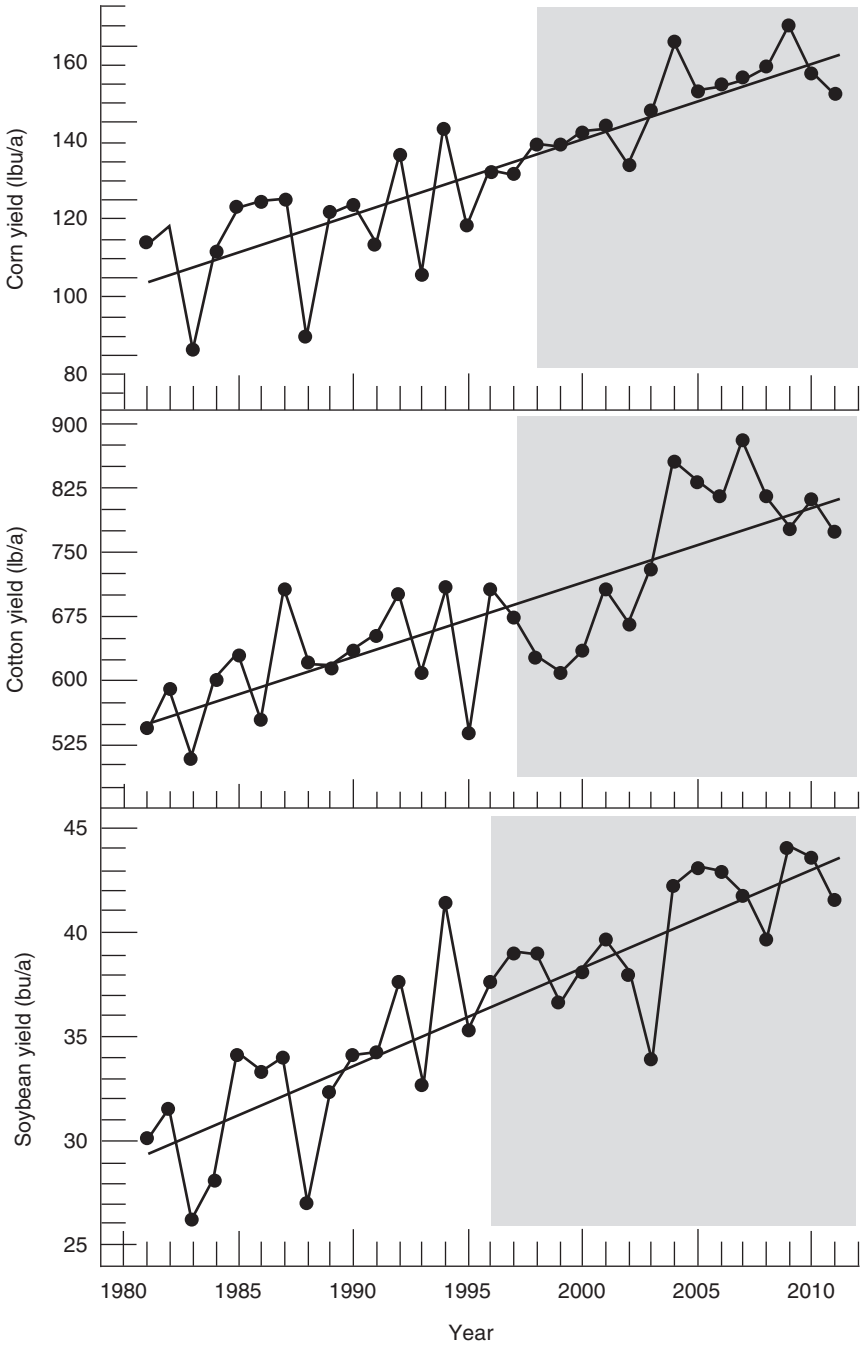

Figure 3 The US yields of the three crops over the past 30 years that are now grown mostly as GR cultivars. The shaded represents the years since the introduction of each GR crop. Reproduced with permission from Duke, S.O., Lydon, J., Koskinen, W.C., *et al.*, 2012b. Glyphosate effects on plant mineral nutrition, crop rhizosphere microbiota, and plant disease in glyphosate-resistant crops. Journal of Agricultural and Food Chemistry 60, 10375–10397. Copyright 2012 American Chemical Society.

non-HR crops (Ervin *et al.*, 2010). Adoption of GR crops has resulted in reductions in soil loss, fossil fuel use, and use of less toxicologically benign herbicides.

The primary reason for tillage is weed management. Other than removing land from its natural state, the most destructive practice in agriculture has been soil loss by wind and water after tillage. Pollution due to loss of applied fertilizers is also exacerbated by tillage, as is loss of soil microbial life and soil organic matter. Postemergence herbicides facilitate reduced- or no-tillage agriculture. Thus, GR crops are ideal for reduced- or no-tillage agriculture, as glyphosate is used only as a post-emergence herbicide that kills almost all weed species. After GR crops were introduced in the Americas, adoption of reduced tillage in those crops greatly increased, especially in cotton and soybean (Bonny, 2011; Derpsch *et al.*, 2010; Dill *et al.*, 2008; Fernandez-Cornejo *et al.*, 2012; Givens *et al.*, 2009;

Locke *et al.*, 2008; Penna and Lema, 2003; Powles, 2008a). Furthermore, the use of complete no-tillage agriculture was twice as high with GR soybean as with conventional soybean (Fernandez-Cornejo and McBride, 2002). In Argentina, there was a one-to-one ratio between adoption of GR soybeans and no-tillage soybeans between 1996 and 2005 (Trigo and Cap, 2006). As long as the glyphosate/GR weed management system was robust, tillage was less valuable, but the advent of evolved GR weeds and shifts of naturally tolerant weed species in GR crop fields has made tillage more desirable as a component of a diversified weed management system, although it is recommended that farmers not abandon conservation tillage systems when GR weeds become a significant problem (Shaw *et al.*, 2012). Nevertheless, the use of reduced- or no-tillage methods in GR crops may wane somewhat in coming years unless other postemergence herbicides can substitute for tillage to control GR weeds.

Another aspect of reduced tillage with GR crops is reductions in fossil fuel use. Tillage requires considerable use of fuel, as do multiple trips across a field to spray the several herbicides that glyphosate replaced. GR crop use in 2005 was estimated to reduce carbon emissions approximately the same as the removal of four million family automobiles from the road (Brookes and Barfoot, 2006). Indirectly, yet another environmental benefit of reduced tillage in parts of South America is a shortening of the production cycle, enabling farmers to plant a crop of soybeans immediately after a wheat crop in the same growing season (Brookes and Barfoot, 2012). The resulting additional crop production on the same unit of land reduces the amount of land that must be converted from the natural state to farmland in order to feed the world.

Although the effects of GR crops on the volume of herbicides used per unit area of land has been debated (Benbrook, 2012; Brookes and Barfoot, 2006), it is clear that adoption of these crops resulted, at least in part, in a large decrease in the use of other herbicides where GR crops were adopted (**Figure 2**). This is particularly apparent with soybeans (**Figure 2(c)**). As mentioned earlier, glyphosate is considered a low-toxicity pesticide with a relatively high LD_{50}. Gardner and Nelson (2008) calculated the reduction in LD_{50} doses per unit area that were caused by transition from conventional to GR crops in the US. The reductions averaged 720 and 248 LD_{50} doses per ha with maize and cotton, respectively. More recently, Bonny (2011) determined the changes in environmental impact quotient (EIQ), a function based on several factors other than LD_{50} values (Kovach *et al.*, 1992), in the US soybean before and after the adoption of GR soybeans (**Figure 4**) and found that EIQ values of herbicide use decreased significantly after adoption. The EIQ levels began to increase somewhat during the past few years, due to increases in quantities of glyphosate sprayed. A detailed analysis of the adoption of GR crops (canola, cotton, maize, and soybean) on the environmental impact (total, farm worker impact, consumer impact, and ecology impact) found reductions of 7–62%, depending on the crop and environmental factor (Kleter and Kuiper, 2003). A more recent analysis of changes in herbicide use associated with GR soybeans in the US found reductions in the use of herbicides that were more toxicologically and environmentally hazardous (Fernandez-Cornejo *et al.*, 2012). Analyses of potential environmental benefits of adoption of GR crops in Europe have also estimated significant environmental and toxicological benefits (Devos *et al.*, 2008; Kleter *et al.*, 2004). Another component of environmental toxicity that favors glyphosate is the relatively short half-life and low leaching capability in soil of glyphosate compared with many of the herbicides that it has replaced (reviewed by Borggaard and Gimsing, 2008; Cerdeira and Duke, 2006; Duke and Cerdeira, 2005).

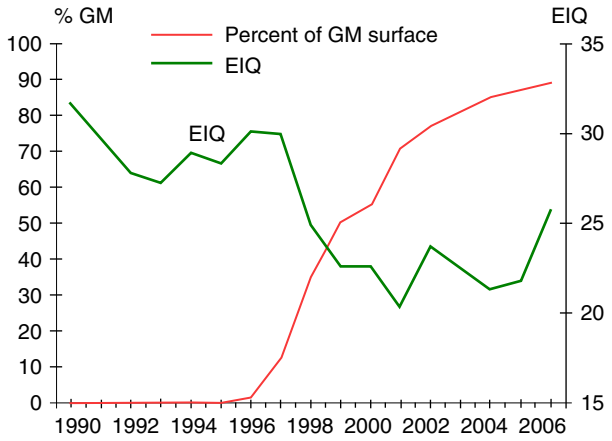

Figure 4 Changes in the EIQ of soybean from 1990 to 2006 (field value per ha). EIQ is a composite pesticide-risk indicator: The higher the EIQ, the higher the environmental and toxicological impact. Reproduced with permission from Bonny, S., 2011. Herbicide-tolerant transgenic soybean over 15 years of cultivation: Pesticide use, weed resistance, and some economic issues. The case of the USA. Sustainability 3, 1302–1322.

Glyphosate-resistant crops and mineral nutrition

Several years after induction of GR crops, several studies indicated that glyphosate causes reduced levels of certain minerals, especially Mn and Ni, in GR crops (e.g., Zobiole *et al.*, 2010 a,b,c, 2011a, 2012; Bellaloui *et al.*, 2009; Bott *et al.*, 2008). Most of these studies were conducted in greenhouse and have been used as support for claims of decreased yields and other adverse effects of glyphosate on GR crops (e.g., Huber, 2007; Johal and Huber, 2009). Other research groups have found no effects of glyphosate on mineral nutrition in GR crops (e.g., Bailey *et al.*, 2002; de Andrade and Rosolem, 2011; Duke *et al.*, 2012a; Henry *et al.*, 2011; Loecker *et al.*, 2010; Rosolem *et al.*, 2010; Serra *et al.*, 2011). A thorough analysis of this topic was made by Duke *et al.* (2012b). They concluded that although there is conflicting literature on this topic, most of the literature indicates that there is no effect and that yield data on GR crops (**Figure 3**) do not support the view that there are significant effects of the transgenes for glyphosate resistance or glyphosate on GR crop mineral nutrition.

Glyphosate-resistant crops and crop disease

Various claims have been made about plant disease in GR crops (reviewed by Duke *et al.*, 2007, 2012b). There is no evidence that the genes used to produce GR crops have any influence on susceptibility of GR crops to disease. Claims of

Table 2 Glyphosate influences and lack of influence on plant disease in glyphosate-resistant crops

Crop	*Disease organism*	*Effect*	*Reference*
Soybean	*Phakopsora pachyrhizi*	Decreased	Feng *et al.* (2005, 2008)

		No effect	Barnett *et al.* (2011)

[a]No effect or increased, depending on the variety.

increases in disease of these crops is due in part to the fact that glyphosate makes non-GR plants more susceptible to plant pathogens, due to inhibited production of compounds from the shikimate pathway that are used by the plant for protection from pathogens (Duke *et al.*, 2007). Because of this effect, non-GR plants are more susceptible to glyphosate in soil with pathogens than in sterilized soil (e.g., Schafer *et al.*, 2012a). This phenomenon has been proposed as an important contributor to the mode of action of glyphosate.

However, glyphosate does not alter the levels of disease-fighting shikimate derivatives in GR crops, and glyphosate acts as a fungicide, albeit a weak one, on some plant pathogens (Duke *et al.*, 2007; Dill *et al.*, 2010). Fungi across several taxa of plant pathogenic fungi have EPSPS enzymes that are similar to those of plants, and the EPSPS of Asian soybean rust (ASR) is sensitive to glyphosate (Dill *et al.*, 2010). Thus, there is reason to hypothesize that GR crops sprayed with glyphosate would have less of some diseases than the same crops without herbicide treatment. There are more papers supporting this hypothesis than those that do not (**Table 2**). Of special interest are the papers showing that glyphosate used on GR crops can have preventative and curative effects on rust diseases in GR maize, soybean, and alfalfa (Anderson and Kolmer, 2005; Dill *et al.*, 2010; Feng *et al.*, 2005, 2008; Samac and Foster-Hartnett, 2012). Glyphosate also protected GR alfalfa from foliar diseases caused by *Colletotrichum trifolii* and *Phoma medicaginis* (Samac and Foster-Hartnett, 2012).

Proof of a direct effect of glyphosate on ASR was obtained by measuring shikimate levels in ASR-infected soybeans with and without glyphosate treatment (Dill *et al.*, 2010). No shikimate accumulated in noninfected plants treated with glyphosate or in non-ASR-inoculated plants without glyphosate, but high levels did accumulate in inoculated plants treated with glyphosate. These results are most clearly interpreted as the shikimate being derived from inhibition of fungal EPSPS.

Johal and Huber (2009) and Kremer and Means (2009) had suggested that glyphosate treatment of GR soybeans increases fungal root diseases (e.g., *Fusarium* spp.). However, several studies reported no effects of glyphosate on *Fusarium virguliforme* (formerly known as *F. solani*) in GR soybeans (**Table 2**). Powell and Swanton (2008) concluded that there was insufficient evidence to conclude that glyphosate promotes infection of GR soybeans by *Fusarium* spp.

An extensive analysis of the published data concluded that the baseline disease resistance or susceptibility of the host plant variety is the major contributor to disease susceptibility in GR crops regardless of the presence of the glyphosate resistance gene or treatment with glyphosate (Duke *et al.*, 2012b). In fact, the reports listed in **Table 2** would suggest that glyphosate treatment can reduce the effects of many plant pathogens on GR crops, whereas having no effect on most others.

Weed shifts, volunteer glyphosate-resistant crops and evolution of glyphosate-resistant weeds

GR crops were initially extremely successful in managing the problematic weed species in those crops. Farmers used this economical and highly effective weed management system year after year. This behavior may have been reinforced by the mistaken view that evolution of resistance would occur very slowly, if at all (Bradshaw *et al.*, 1997). But nature abhors a vacuum, so weeds that could exist in the vacuum caused by year after year use of glyphosate/GR crop cropping systems moved into the ecological niches vacated by those species that were effectively controlled (weed shifts). Weed species shifts involved perennial weeds that were less sensitive to glyphosate, such as nutsedges (*Cyperus* spp.), shifts to weeds with more natural resistance (tolerance) to glyphosate, such as morning glory species (*Ipomoea* spp.), and shifts to weeds that germinate after glyphosate is normally sprayed, such as *Solanum ptychanthum* (Reddy and Norsworthy, 2010). Some weed species fit into more than one of these categories. Analysis of surveys of prevalent weeds in agronomic crops before and more than 10 years after adoption of GR cultivars of the same crops in the southern US concluded that major changes in weed species were primarily due to use of glyphosate, via both weed shifts and evolution of resistance (Webster and Nichols, 2012). The changes were less drastic in maize, for which adoption was slower (**Figure 1**).

Glyphosate had been used for 22 years before the introduction of GR crops. It was used intensively year after year for weed management before or after harvest and with woody crops such as grapes and fruit tree orchards. Ironically, the first case of evolved resistance to glyphosate (*Lolium rigidum* in Australia – Powles *et al.*, 1998; Pratley *et al.*, 1999) was reported soon after the paper claiming that evolved resistance was highly improbable (Bradshaw *et al.*, 1997). At present, there are 24 weed species that have evolved resistance to glyphosate (**Figure 5**; **Table 3**). During first few years of this increase, evolution of resistance did not occur in GR crops, but most of the cases of evolved resistance in the past decade have been in GR crop fields where farmers have used glyphosate year after year in the same crop or in alternating GR crops in the same field.

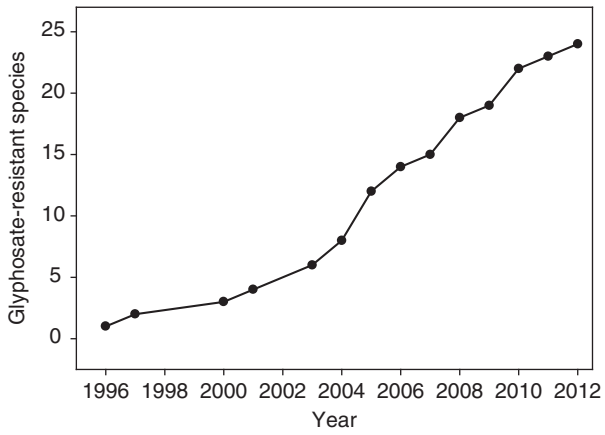

Figure 5 Cumulative number of weed species that have evolved resistance to glyphosate worldwide. Data from Heap, I., 2013. International Survey of Herbicide Resistant Weeds. Available at: www.weedscience.org (accessed 30.05.13).

Bradshaw *et al.* (1997) were correct in that a one base pair change in a codon of the EPSPS gene would not impart the robust level of resistance reported on herbicide classes targeting more resistance-prone enzymes. The odds that the two codon mutations needed for a robust but resistant form of EPSPS to occur in nature are indeed extremely remote, and none of the 24 species of evolved GR weeds has been documented to be resistant via such a mechanism. The confirmed mechanisms of evolved resistance to glyphosate are: (1) single-codon changes in the gene for EPSPS, (2) gene amplification of the gene for EPSPS, and (3) reduced translocation due to sequestration of glyphosate into the vacuoles of treated leaves (Shaner *et al.*, 2012).

There are several cases of single base pair mutations of the EPSPS gene providing a low level of glyphosate resistance. For example, resistance to glyphosate in *E. indica* L. is caused by a single-codon change (Pro_{106} to Ser) in the EPSPS gene, providing a 5-fold decrease in sensitivity to glyphosate (Baerson *et al.*, 2002). The same amino acid change in EPSPS was found in a GR *L. rigidum* biotype (Simarmata and Penner, 2008) and a GR *Amaranthus tuberculatus* (Nandula *et al.*, 2013). A Pro_{106} to Thr substitution in EPSPS was identified in another GR *L. rigidum* biotype (Wakelin and Preston, 2006), and this change was also reported in another *E. indica* biotype (Ng *et al.*, 2003). None of these one-codon changes provides a high level of resistance.

Another mechanism that involved the glyphosate target is that of greatly increased amounts of EPSPS enzyme due to gene amplification, so that field rates of glyphosate cannot inhibit enough of the *in vivo* enzyme activity to inhibit the shikimate pathway. The first case of this was in *A. palmeri* in GR crops in the US, where this weed evolved a high level (up to 8-fold in the laboratory and more than 12-fold in the field) of resistance to glyphosate (Culpepper *et al.*, 2006). Another GR biotype of *A. palmeri* was at least 20-fold less sensitive to glyphosate than the wild type (Whitaker *et al.*, 2007). Gaines *et al.* (2010) found that individual plants of the resistant biotype populations had a range of extra copies of the EPSPS gene, from 5 to 160 additional copies. The extra genes were scattered throughout the genome with copies on every chromosome. The extra gene copies (gene amplification) correlated positively with additional EPSPS mRNA, enzyme protein, and enzyme activity, thus requiring significantly more glyphosate to effectively shut down the shikimate pathway. More recently, amplification of the copy number of EPSPS has helped to evolve GR *L. perenne* spp. *multiflorum* (Salas *et al.*, 2012) and *Kochia scoparia* (Wiersma, 2012), with up to 25 and 9, respectively, extra copies of the gene. In both cases, the extra gene copies resulted in additional EPSPS enzyme activity. Preliminary data indicate that at least one mechanism of glyphosate resistance in an evolved *A. tuberculatus* biotype is due to gene amplification of EPSPS (Tranel *et al.*, 2011).

Reduced translocation of glyphosate to meristems and young, developing tissues occurs in some species that have evolved resistance to glyphosate; for example, *Conyza bonariensis* (Dinelli *et al.*, 2008), *Conyza canadensis* (Feng *et al.*, 2004 and others), and *L. multiflorum* (Lorraine-Colwill *et al.*, 2003;

Table 3 Weed species that have evolved resistance to glyphosate

Weed species	*Location (countries)*	*Year*
Amaranthus palmeri	USA	2005
Amaranthus spinosus	USA	2012
Amarnathus tuberculatus (syn *rudis*)	USA	2005
Ambrosia artemisiifolia	USA and Canada	2004
Ambrosia trifida	USA and Canada	2004
Bromus diandrus	Australia	2011
Chloris truncata	Australia	2010
Conyza bonariensis	South Africa, Spain, Brazil, Israel, Columbia, USA, Australia, Greece, and Portugal	2003
Conyza canadensis	USA, Brazil, China, Spain, Czech Republic, Poland, Canada, Italy, and Greece	2000
Conyza sumatrensis	Spain, Brazil, and Greece	2009
Cynodon hirsutus	Argentina	2009
Digitaria insularis	Paraguay and Brazil	2008
Echinochloa colona	Australia, USA, and Agentina	2007
Eleusine indica	Malaysia, Colombia, China, USA, and Argentina	1997
Kochia scoparia	USA and Canada	2007
Leptochloa virgata	Mexico	2010
Lolium multiflorum	Chile, Brazil, USA, Spain, and Argentina	2001
Lolium perenne	Argentina	2008
Lolium rigidum	Australia, USA, South Africa, France, Spain, Israel, and Italy	1996
Parthenium hysterophorus	Columbia	2004
Plantago lanceolata	South Africa	2003
Poa annua	USA	2010
Sorghum halepense	Argentina and USA	2005
Urochloa panicoides	Australia	2008

Wakelin *et al.*, 2004). Reduced translocation in both GR *Lolium* spp. and *C. canadensis* may be associated with sequestration of glyphosate into the vacuoles of cells of the treated leaves (Ge *et al.*, 2010, 2011, 2012). Much less or no vacuolar sequestration of glyphosate is seen in susceptible biotypes. In *C. canadensis*, low temperatures reduce the sequestration of glyphosate, causing loss of resistance (Ge *et al.*, 2011). Vacuolar sequestration is probably due to a membrane transporter, similar to the case of a GR *Escherichia coli* with overexpression of a gene for a glyphosate membrane transporter (Staub *et al.*, 2012).

Some plants can slowly metabolize glyphosate to relatively much less toxic or completely nontoxic metabolites (Duke, 2011a). Thus, genes encoding enzymes that will detoxify glyphosate exist in some plant species, although neither the genes nor enzymes have been characterized. Enhanced metabolic degradation of glyphosate has been looked for but has not been found to be a mechanism of evolved resistance to date (Duke, 2012; Perez-Jones and Mallory-Smith, 2010). One laboratory has claimed that enhanced resistance has been involved in resistance of two different weed (*Digitaria insularis* – de Carvalho *et al.*, 2011; *C. canadensis* – Gonzalez-Torralva *et al.*, 2012) and one crop species (*Mucuna pruriens* – Rojano-Delgado *et al.*, 2012), although conclusive proof of the metabolites was not provided in these papers. In each of these cases, metabolism of glyphosate was reported to occur by both a GOX enzyme to produce AMPA and a C-P lyase enzyme that produced sarcosine, something that had not been identified in previous studies with other species, including studies with *C. canadensis* (Feng *et al.*, 2004). If the results of these papers can be corroborated, metabolism of glyphosate can be added to the mechanisms of evolved resistance. Metabolism-based herbicide resistance is very common for most other herbicide resistances, and many of these are based on cytochrome P450 monooxygenases (Powles and Yu, 2010).

In some biotypes of *Ambrosia trifida* L. that have evolved resistance to glyphosate, this normally slow-acting herbicide causes rapid necrosis of the foliage to which it is applied (Robertson, 2010). This limits translocation of the herbicide to meristems and developing tissues, allowing a phoenix-like regrowth from the mostly desiccated plant. The physiological/biochemical basis of the very rapid effect of glyphosate in treated tissues of this biotype is unknown. Very few plant species, such as sugar beet (*Beta vulgaris* L.), have a similar rapid response to glyphosate (Madsen *et al.*, 1995).

Volunteers of GR crops can be significant problems in GR crops of a different species the next year (Reddy and Norsworthy, 2010). Problems with volunteer GR maize in GR sugar beet (Kniss *et al.*, 2012), volunteer GR maize in GR soybean (Marquardt *et al.*, 2012), volunteer GR soybean in GR cotton (Lee *et al.*, 2009b), and with volunteer GR cotton in GR soybeans (Lee *et al.*, 2009a) have been documented. GR crops in non-GR crops, such as GR soybean in non-GR rice (Bond and Walker, 2009) and GR canola in non-GR wheat (Lawson *et al.*, 2006), can also be a problem. Volunteer crops seldom persist for more than a year. But, in some climates, some HR crop species could become weeds that persist for several seasons, due to persistence of seeds in the seed bank, as has been the experience with GR canola in California (Munier *et al.*, 2012). One could assume that this has nothing to do with the transgenic trait, other than making it impossible to control the volunteer crop with the herbicide to which it has been made resistant.

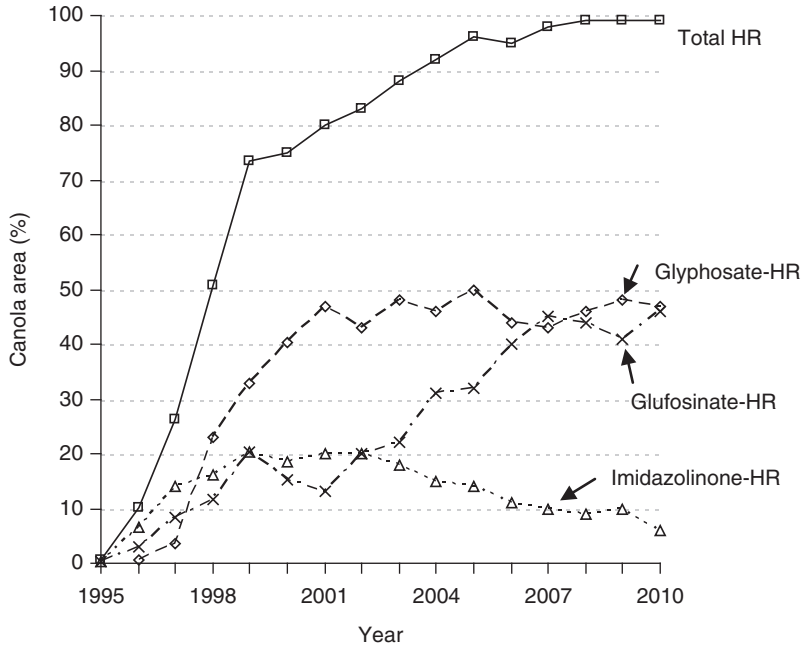

Figure 6 Adoption of herbicide-resistant oilseed rape (*Brassica napus* L.) in Canada: Mainly grown in Alberta, Saskatchewan, and Manitoba. Reproduced from Beckie, H.J., 2011. Herbicide-resistant weed management: Focus on glyphosate. Pest Management Science 67, 1037–1048, with permission from Wiley Press, Chichester, UK.

Using the same weed management technology year after year is not feasible in the long run, due to weed shifts and evolutionary processes. The clear initial superiority of weed management with GR crops is being compromised by the long-term use of one or more GR crops, with little or no weed management diversity (Powles, 2008a, b). The economic and environmental advantages of this technology are being diminished due to these developments (Carpenter and Gianessi, 2010; Shaw *et al.*, 2012). Additional weed management costs can be more than $70/ha with some GR weeds (e.g., *A. palmeri*) in some crops (e.g., cotton). Clearly, strong emphasis will have to be made on instituting more diverse weed management strategies in order to preserve the high value of GR crops in weed management technology. For example, canola farmers of Canada have had access to herbicide resistant canola since 1996 but have never planted more than 50% GR canola (**Figure 6**), instead they have planted a significant amount of imidazolinone- and glufosinate-resistant canola. Also, there was a small amount (never more than 1%) of bromoxynil-resistant canola grown in 2000 and 2001 (Beckie *et al.*, 2006). The more diversified weed management used in Canadian canola, using other HR canola varieties and crop rotation, has probably been the reason that no GR weeds have evolved from selection in Canadian canola (Beckie, 2011, Hugh Beckie, personal communication, May, 2013). Strategies involving use of herbicides for which evolution of resistance is less likely are needed (Beckie and Tardif, 2012). Both the need for diversity and the increases in GR weeds and weed species shifts are causing farmers to supplement GR crop-based weed management with older technologies such as selective herbicides and tillage. A recent survey of 1299 US farmers who grow GR crops reported that they perceived tillage to be a more effective management method for GR weeds than it actually is (Prince *et al.*, 2012). Some of these strategies will also include new HR crops with new herbicide resistance traits that can be used with or instead of glyphosate alone with GR crops. The new HR crop technologies that will soon be available are described in the next main section, and HR crop technologies that might follow them are discussed.

Gene flow from glyphosate-resistant crops

A possible means of production of GR weeds is gene flow of the resistance transgene from the crop to a weedy relative and subsequent introgression of the transgene from the cross into the weed population. The only GR crop in which flow of a transgene to a weedy relative has been documented in the field is canola (Warwick *et al.*, 2008), although this has not created a significant weed problem. No gene flow has been reported in cotton or soybeans. In maize, there were disputed cases of gene flow to teosinte and land races of maize in Mexico (e.g., Ortiz-García *et al.*, 2005); however, if this occurred, it has not created a GR weed problem. The biggest problem with canola and maize is gene flow from the GR crop to non-GR varieties (Gealy *et al.*, 2007), which causes trade problems when the adventitious presence of the transgene in harvested non-GR crops exceeds allowable limits. There are feasible 'fail-safe' approaches utilizing multiple technologies to stop gene flow (Gressel and Al-Ahmad, 2005), but the seed industry has yet to adopt such methods. One can speculate that the greater potential for gene flow to weedy relatives in rice and wheat (see Section Nontransgenic Herbicide-Resistant Crops) may have played a part in the decision to not commercialize GR varieties of these crops.

Presumably, a herbicide resistance transgene will not cause ecological disruption in a natural setting where the herbicide is not used; however, where the herbicide is used, it can facilitate

introgression of all transgenes in a crop to a wild species. If there is a benefit in a natural setting of a nonherbicide resistance transgene, such as insect resistance, the herbicide can provide the temporary protection needed for even relatively unfit crosses to persist (Londo *et al.*, 2011). Herbicide resistance genes can flow not only from HR crops but also from resistant weeds to other weed species. For example, Zelaya *et al.* (2007) found gene flow between GR *C. canadensis* to *Cylindropuntia ramosissima* could occur, followed by introgression of resistance into *C. ramosissina*.

The case of unintended gene flow from experimental plots of GR creeping bentgrass (*Agrostis stolonifera* L.) being developed for its use in turf to wild bentgrass (Snow, 2012; Watrud *et al.*, 2004) illustrates that, once genes escape to wild populations, they can spread in unexpected ways and cannot be called back. Not only the *cp4* gene for glyphosate resistance is prevalent in some feral populations of bentgrass after escape of the gene in 2002 (Reichman *et al.*, 2006), but also a GR hybrid between feral bentgrass (pollen receptor) and rabbitfoot grass (*Polypogon monspeliensis*) (pollen donor) has occurred (Zapiola and Mallory-Smith, 2012). Such gene flow events portend significant weed management problems in GR crops due to gene flow if care is not taken.

Crops Made Resistant to Auxinic Herbicides

Auxinic herbicides are those that act in some ways like the endogenous plant hormone indoleacetic acid, which is also called auxin (Fedtke and Duke, 2005). There are several types of auxinic herbicides, and crops are being made resistant to two of these, namely dicamba and 2,4-D, with transgenes that encode enzymes that inactivate the herbicide. Target site resistance is an unlikely option for these crops, as auxinic herbicides bind several F-box proteins that are regulatory in nature (Gleason *et al.*, 2011; Walsh and Schmitzer, 2012). Which of these receptors are bound varies between herbicides. Making sufficient binding sites resistant to the herbicide would probably require several transgenes.

Dicamba-resistant crops

Dicamba (3,6-dichloro-2-methoxybenzoic acid) is an older auxinic herbicide, killing mainly broadleaf weed species in monocot grain crops. It is too phytotoxic for its use as a postemergence herbicide in maize, in which it can only be used as a preplant herbicide with a delayed planting to avoid injury to the crop. It controls more weed species than most other auxinic herbicides, such as 2,4-D, and even controls more species than glufosinate (Feng *et al.*, 2010). Dicamba-resistant crops have been generated by inserting a transgene from a soil microbe (*Stenotrophomonas maltophilia*) that encodes dicamba monooxygenase (DMO) (Behrens *et al.*, 2007). This enzyme demethylates dicamba to form nonphytotoxic 3,6-dichlorosalicylic acid. The gene provides a high level of resistance to dicamba in both dicots (cotton and soybean) and monocots including maize (Cao *et al.*, 2011). Dicamba resistance will be stacked with glyphosate and/or glufosinate resistance in cotton and soybeans in the first introductions.

Dicamba provides excellent control of some of the weed species that have evolved resistance to glyphosate, for example, *C. canadensis* (Kruger *et al.*, 2010) and *A. trifida* (Vink *et al.*, 2012). There are relatively few cases of evolved resistance to dicamba: *Sinapis arvensis* (Yajima *et al.*, 2004); *K. scoparia* (Goss and Dyer, 2003; Nandula and Manthey, 2002; Preston *et al.*, 2009); *Galeopsis tetrahit* (Weinberg *et al.*, 2006); *Chenopodium album* (Rahman *et al.*, 2008); and *Lactuca serriola* (Burke *et al.*, 2009). However, one of these species (*K. scoparia*) has also evolved resistance to glyphosate (**Table 3**). Dicamba resistance will provide a useful tool in diversification of weed management, but the cases of evolved dicamba resistance already reported indicate that overuse of this new tool will eventually bring about problems with evolved dicamba resistance.

Another concern is that aerial drift of dicamba to dicamba-sensitive crops and other nontarget vegetation will pose economic and environmental problems (Egan and Mortensen, 2012). Some plant species are very sensitive to very low exposures to auxinic herbicides as can be experienced by vapor drift. However, dicamba has been used for more than 40 years as a postemergence spray, and it is still used extensively (USGS, 2013) without overwhelming problems. Vapor drift can be reduced significantly with a diglycolamine formulation (Egan and Mortensen, 2012). Low-volatility formulations may be required for use with dicamba-resistant crops.

2,4-Dichlorophenoxyacetic acid-resistant crops

Crops are also being made resistant to one of the oldest herbicides, 2,4-D. Like dicamba, resistance is provided by the use of a transgene derived from a microbe that encodes an enzyme that detoxifies the herbicide. Several microbes (*Ralstonia eutropha*, *Sphingobium herbicidivorans*, and *Delfiia acidovorans*) have genes encoding an aryloxyalkanoate dioxygenase (AAD) that converts 2,4-D into dichlorophenol, a nonphytotoxic compound (Llewellyn and Last, 1996; Wright *et al.*, 2010). Variants of this enzyme also detoxify other auxinic herbicides, such as triclopyr and fluroxypyr, as well as AOPP grass-killing, ACCase-inhibiting herbicides such as quizalofop. The first 2,4-D-resistant crops will be maize and soybeans with an AAD transgene for 2,4-D resistance stacked with genes for glyphosate and/or glufosinate resistance (**Table 4**). AAD from different microbes vary in their efficiency in detoxifying 2,4-D and AOPP herbicides. The AAD from *S. herbicidivorans* provides the best 2,4-D resistance in crops, but it is not sufficiently active against the herbicidal enantiomers of AOPP herbicides to provide resistance (Wright *et al.*, 2010).

Plans have been made for marketing 2,4-D-resistant maize, soybean, and cotton (Robinson *et al.*, 2012). AOPP- and 2,4-D-resistant maize and glufosinate- and 2,4-D-resistant soybeans have been approved by Canadian authorities but will not be sold until after 2013. Crops with three herbicide resistances (2,4-D, glufosinate, and glyphosate) are under development (**Table 4**). The possibility of unacceptable herbicide drift problems with 2,4-D- and dicamba-resistant crops has slowed the deregulation (approval) process for these crops due to the United States Department of Agriculture (USDA) Animal and Plant Health Inspection Service's recent (as of early 2013) requirement that both products undergo an environmental impact study. So, the earliest introduction of 2,4-D-resistant crops in the US will probably be in 2015.

As with dicamba, drift of 2,4-D to nontarget natural vegetation and other crops has been a problem since 2,4-D was

Table 4 Herbicide-resistant crops for which petitions for deregulated status (approval for commercialization) have been filed but not yet granted (APHIS, 2013)

Year of application	*Herbicides*
Maize	
2009	2,4-Dichlorophenoxyacetic acid (2,4-D) and acetyl-CoA carboxylase inhibitors
2011	Glufosinate
2011	Glyphosate
Soybean	
2009	Glyphosate and isoxaflutole (hydroxyphenylpyruvate dioxygenase (HPPD) inhibitor)
2009	2,4-D and glufosinate
2009	Imdazolinone (acetolactate synthase inhibitor)
2010	Dicamba
2011	2,4-D, glyphosate, and glufosinate
2012	HPPD inhibitor and glufosinate
Cotton	
2012	Dicamba and glufosinate
Canola	
2011	Glyphosate

introduced in the mid-1940s and sold as amine or ester formulations. These formulations of 2,4-D are still used in large amounts for weed management. 2,4-D choline, a quaternary ammonium salt with much lower volatility than previous 2,4-D products, is planned to be the only formulation allowed with 2,4-D-resistant crops. Thus, introduction of this low-volatility formulation of 2,4-D could even decrease the 2,4-D drift problem with non-GRC uses.

As pointed out by Egan *et al.* (2011), there are almost 20 weed species that have evolved resistance to 2,4-D. In fact, the first two reported cases of evolved herbicide resistance were of 2,4-D in 1957 (Heap, 2013). Beckie and Tardif (2012) considered 2,4-D and other auxinic herbicides to have a lower risk for evolution of resistance than some other herbicide classes. In at least some cases, a single, dominant gene confers resistance to more than one auxinic herbicide (Jugulam *et al.*, 2005). Considering that auxinic herbicides appear to have multiple binding sites (Walsh and Schmitzer, 2012), single-gene-based resistance may be due to an enzyme that degrades the herbicide (Harrington and Wooley, 2006), but other mechanisms of resistance have apparently evolved (Kelley and Riechers, 2007). Weeds have had more than 60 years to evolve resistance to this still heavily used herbicide. Clearly, 2,4-D resistance neither does not evolve as readily as resistance to ACCase or ALS inhibitor herbicides does nor perhaps as slowly as to glyphosate.

Other Transgenic Herbicide-Resistant Crops

There are patents and publications on many genes for resistance to almost all herbicide classes. Only a few of these are likely to be developed and commercialized. Crops made resistant to hydroxyphenylpyruvate dioxygenase (HPPD)-, ACCase-, and ALS-inhibitor herbicides will probably be commercialized, so these are dealt with separately in this section; others are discussed in the last section.

Hydroxyphenylpyruvate dioxygenase inhibitor-resistant crops

More than 20 years ago, the last group of herbicides with a new mode of action was commercialized. They were inhibitors of HPPD, an enzyme that produces homogentisic acid, a precursor for plastoquinone (PQ) and vitamin E (Duke, 2012). PQ is needed as a cofactor for phytoene desaturase (PD), a key enzyme in carotenoid synthesis, and as an electron transport component of PSII. The symptoms of complete bleaching of leaves are much like those of PD inhibitors (Arias *et al.*, 2005). Several transgenic approaches to make crops resistant to these herbicide have been successful, including overexpression of a bacterial HPPD, use of a mutant plant enzyme that is resistant through bypassing HPPD in the synthesis of homogentisic acid with three bacterial genes, and, finally, overexpression of HPPD plus enhancing HPPD substrate (*p*-hydroxyphenylpyruvate) levels with a transgene for yeast prephenate dehydrogenase (Matringe *et al.*, 2005). HPPD HR crops for which petitions of deregulation have been filed are soybean with stacked glyphosate resistance and another with stacked glufosinate resistance (**Table 4**). Maize is naturally resistant to some HPPD inhibitor herbicides through rapid detoxification of the herbicide and a less sensitive form of HPPD than most weeds (Grossmann and Ehrhardt, 2007). Only two weed species have evolved resistance to HPPD-inhibitor herbicides (*A. palmeri* and *A. tuberculatus* (syn. *rudis*) (Heap, 2013). Unfortunately, there are HPPD-resistant biotypes of *A. tuberculatus* with multiple resistances with up to four additional resistances, including resistance to glyphosate, in all combinations (Hausman *et al.*, 2011; Tranel *et al.*, 2011).

Acetyl-CoA carboxylase inhibitor-resistant crops

As mentioned in the Section 2,4-Dichlorophenoxyacetic acid-resistant crops, the same genes that encode the degradation enzyme ADD can provide resistance to AOPP herbicides that inhibit ACCase (Wright *et al.*, 2010). The company developing crops using these genes has chosen to introduce 2,4-D-resistant crops first, although one of their petitions for deregulation is for 2,4-D- and ACCase inhibitor-resistant maize (**Table 4**). Nontransgenic crops made resistant to ACCase inhibitors via mutation of ACCase were never very successful (Martino-Catt *et al.*, 2012), and weeds evolve target-site resistance to AOPP herbicides relatively rapidly (Beckie and Tardif, 2012; Heap, 2013). Some plant species (e.g., *L. rigidum*) have evolved rapid degradation of AOPP herbicides (Yu *et al.*, 2013).

Transgenic crops resistant to acetolactate synthase inhibitors

HR crops with resistance to ALS inhibitors have been developed (Green *et al.*, 2008) and brought to the deregulation stage. These HR crops have the *hra* transgene that encodes a form of ALS with two amino acid substitutions that is highly resistant to sulfonylureas, providing more than 10 000-fold resistance to chlorimuron in maize and very high levels of resistance to nicosulfuron and tribenuron in soybean (Lee *et al.*, 1988; Green *et al.*, 2008). Maize with both glyphosate

and ALS-inhibitor resistance has been deregulated (APHIS, 2013) but not commercialized yet. A petition for deregulation of transgenic imidazolinone-resistant soybean has been filed (Table 4). Genes for mutated, ALS inhibitor-resistant crops have been introduced into the chloroplast genome (the plastome) (Shimizu *et al.*, 2008). The resulting transformants were resistant to a variety of ALS-inhibiting herbicides. This approach greatly lowers the possibility of transgene flow through pollen, as the plastome is rarely transmitted via pollen.

Unfortunately, the ALS gene is very plastic, with a number of mutations yielding resistant plants that are quite fit in a field situation (Gutteridge and Thompson, 2012). Thus, many weed species have evolved resistance to these herbicides, with an array of cross-resistances (Heap, 2013). Introduction of ALS inhibitor-resistant crops in many cases will increase the selection for weed resistance to these herbicides.

Resistance to other herbicides

There are numerous papers on potential genes for HR crops, such as that of Zhang *et al.* (2012), which describes the microbial gene for an arylamidase that can degrade a number of herbicides with amide groups (e.g., propanil). A few such genes have been used to transform plants in order to successfully impart herbicide resistance. Some examples that are unlikely to result in commercial HR crops in the near future are summarized in Table 5.

Of these, the crops made resistant to protoporphyrinogen oxidase (PPO) herbicides came closest to development and commercialization. PPO inhibitor-resistant maize and rice were generated with a double mutant (two codons) of *Arabidopsis* PPO and were field tested successfully (Li and Nicholl, 2005). Plants with this double mutant were cross-resistant to a range of commercial PPO inhibitors sold by several companies. The developing company proceeded to give these crops a trade name before shelving this technology. The reasons for stopping development have not been made public.

The inability to connect HR crops to a single herbicide may have been a factor that has made some of these possible HR crops too economically risky for introduction. Glyphosate- and glufosinate-resistant crops can only be used with the one herbicide to which the crop is engineered to be resistant, and in each case, the company that sells the seed also produces the herbicide. This was also true with bromoxynil-resistant crops. Thus, the economic equation for HR crops like the PPO inhibitor-resistant crops may be weakened by cross-resistances that allow farmers to buy and use the herbicide that is most economical to them for that crop. This is even more problematic for transgenic HR crops with inactivation genes such as gene for human cytochrome P450 monooxygenases that confer resistance to many herbicides with different chemical structures and modes of action (Inui *et al.*, 2001). In the case of dicamba- and 2,4-D-resistant crops, tying the use of the HR crops to proprietary, low-volatility formulations of the herbicides can improve both the stewardship and economic viability of the product for the producing companies.

The Future – Where This Technology May Be in the Next Decade and Beyond

Transgenic crops with resistance to each of three different herbicides (bromoxynil, glufosinate, and glyphosate) have been commercialized. Bromoxynil-resistant crops were discontinued for economic reasons. GR crops have completely dominated the HR crops market, for the reasons discussed above and in Duke and Powles (2008). Most of the worldwide soybean crop is GR, and most of the canola, maize, and cotton crops in the US are GR. The utility of GR crops is waning somewhat due to the increasing numbers of weeds, both evolved and species shifts, that can no longer be adequately managed with glyphosate. There is no product on the horizon that will bring back the combination of simplicity, low cost, excellent efficacy, and reduced environmental impact that was available to farmers by the use of GR crops during the first decade of their use. There is currently no stream of new herbicides with new modes of actions to save the day, as occurred every few years until approximately 20 years ago (Duke, 2012). However, most of the pending petitions for deregulation of transgenic crops in the US are for HR crops (APHIS, 2013).

The next generation of HR crops, with different combinations of stacked genes for resistance to glyphosate, will provide farmers with more flexibility and diversity for weed management, but weed management will become more like the approaches used before the introduction of GR crops. In

Table 5 Some transgenes that have been used to generate herbicide-resistant plants that are unlikely to be commercialized in the near future

Gene/enzyme[a]	*Herbicide(s)*	*Gene source*[b]	*Reference*
Cytochrome P450 (D)	Phenylureas	*Helianthus tuberosus* (P)	Didierjean *et al.* (2002)
	Multiple	*Homo sapiens* (A)	Inui *et al.* (2001)
Dehalogenase (D)	Dalapon	*Pseudomonas putida* (M)	Buchanan-Wollaston *et al.* (1992)
Dihydropteroate synthase (T)	Asulam	*Escherichia coli* plasmid (M)	Joel *et al.* (1995); Surov *et al.* (1998)
Esterase (D)	Pyrimidines	Rabbit liver (A)	Feng *et al.* (1997)
Glutathione *S*-transferase	Alachlor, EPTC, and Dimethenamid	*Zea mays* (P)	Milligan *et al.* (2000)
Hydrolase (D)	Phenmedipham	*Arthrobacter oxydans* (M)	Streber *et al.* (1994)
Phytoene desaturase (T)	Fluridone and norflurazon	*Hydrilla verticillata* (P)	Arias *et al.* (2005)
Protoporphyrinogen oxidase (T)	Acifluorfen	*Arabidopsis thaliana* (P)	Li and Nicholl (2005)
Superoxide dismutase (D)	Paraquat	*Pisum sativum* (P)	Sen Gupta *et al.* (1993)
α-Tubulin (T)	Dinitroanilines	*Eleusine indica* (P)	Anthony *et al.* (1999)

[a]D, detoxification; T, target site.
[b]A, animal; M, microbe; P, plant.

those days, farmers had to use combinations of selective herbicides to control a wide range of weeds on which none of the herbicides was effective alone. All of the herbicides to which the new HR crops are resistant are selective herbicides to which some weeds have already evolved resistance. Multiple resistance of weeds to different combinations of herbicides (Tranel *et al.*, 2011) will make choosing the proper HR crop–herbicide combinations more problematic than selection of the proper selective herbicides for a crop before the introduction of HR crops and the wide-spread evolution of herbicide resistance. Thus, weed management will grow even more complicated than before the advent of GR crops. This problem would have occurred without the introduction of HR crops because most evolution of herbicide resistance would have occurred without HR crops. One can theorize that GR crops have slowed the resistance to other herbicide classes because of the negative impact they have had on their use.

Despite the remarkable success of GR crops, the number of HR crops that have pending petitions for deregulation is not large (**Table 4**). Devine (2005) discussed reasons for the lack of more transgenic HR crops almost 10 years ago. His reasons included the high costs of research and development and regulatory approval, both for the HR crop and the use of the herbicide with that crop. International trade issues were also considered a barrier. An issue that was not mentioned was the incredible success of GR crops, compared with other HR crops. Potential market share in competition with GR crops was also a factor that inhibited introduction of other HR crops, just as the success of GR crops slowed herbicide discovery and development research (Duke, 2012). All of these hindrances still exist, but the rapid evolution of GR weeds is changing the economic equation in favor of development of new HR crops, just as it has for renewed herbicide discovery efforts. It is hard to foresee how weeds will be managed past the next decade, but GR crops will almost certainly still play a major role. Without another major new technology with a success like GR crops, weed management will surely utilize more diverse tools and strategies and become more complex.

Glossary

Adventitious agent A foreign entity that is introduced inadvertently or accidentally. It often refers to viruses, bacteria, or other organisms.
Biopharmaceuticals Drugs based on large biological molecules.
Bioreactor A closed device or system for the culture of cells in an aseptic manner.
Good manufacturing practice (GMP) A system for ensuring that products are consistently produced and controlled according to quality standards.
Monoclonal antibody Single-cell-originated proteins that bind foreign target molecules with high specificity to elicit various immune responses.
***N*-linked glycosylation** Sugar chains added to a secretory protein at the consensus sequence *N*-X-(S/T), where X is any amino acid but proline; it is important for protein stability, activity, trafficking, and targeting as well as pharmacokinetic properties of protein therapeutics.
***O*-glycosylation** Addition of complex sugar residues to the hydroxyl group of serine or threonine on proteins that have completed their folding in the Golgi apparatus.
Plant-made pharmaceuticals (PMPs) Production of biopharmaceuticals in plants.
Vaccines Biological compounds that elicit immunogenic responses to diseases, primarily caused by microorganisms.
Validation The documented act of demonstrating that a procedure, process, and activity will consistently lead to the expected results.

Introduction

Drugs based on large biological molecules, known as biologics or biopharmaceuticals, have been produced in genetically engineered animal and bacterial and yeast cells for more than two decades and the current market for these products exceeds US$149 billion. The growing global demand for biopharmaceuticals is fueling the development of platforms that increase safety, capacity, and flexibility and decrease production costs. The tools of modern plant biotechnology now enable a spectrum of recombinant protein products to be produced in plants, including biopharmaceuticals, and it is widely accepted that plant-made pharmaceuticals (PMPs), or molecular pharming, will help to meet the rising demand. Indeed, plants can now be considered alongside traditional production platforms and may provide numerous potential advantages over microbial and mammalian production systems. These include cost and scale of production, target flexibility, intrinsic safety, and quality of the products. Some of these factors are contrasted in Table 1. By some estimates, PMPs could be produced at 10% of the cost of microbial systems and 0.1% of the cost of mammalian cell culture (Maxmen, 2012). In many cases, production in plants can allow large-scale production that can be adapted to the changing demands of the market. Plants also lack the health risks that can arise from contamination by human pathogens, toxins, or oncogenes that can be harbored in mammalian expression systems.

Plants, like any host system for protein expression, are not a suitable host for production of every class of protein therapeutic, and there are a multitude of factors that can influence the success of PMP production. The key factors influencing protein accumulation include choice of a suitable host species, design and optimization of the protein-coding sequence, selection and optimization of the expression system, the transformation system, plant production and containment, and purification and characterization of the recombinant protein. The spectrum of products in various stages of development in plant production systems, a review of the key factors for successful production of biopharmaceuticals, and a discussion of biosafety considerations will form the subject matter of the following sections. The authors also present a case study to exemplify this process.

Products

Pharmaceutical products engineered for production in transgenic plants are primarily comprised of protein and lipid molecules. In contrast, bioactive small molecules and other plant chemical entities are isolated from the so-called medicinal crops. As eukaryotes, plants have protein-processing machinery similar to mammals and are consequently a good choice to synthesize complex or novel therapeutic proteins. Here the authors discuss the main classes derived from these recombinant protein production systems: therapeutic proteins, vaccines, and antibodies, all with uses that span veterinary and human pharmaceutical applications.

Therapeutic Proteins

Therapeutic proteins refer to pharmacologics used to treat a clinical issue derived from a biochemical deficiency. Examples include enzymes, hormones, structural proteins, antimicrobial agents, etc. (Nagels *et al.*, 2012; Thomas *et al.*, 2011).

The first demonstration that production of a relevant therapeutic protein was possible in a variety of plant species

Table 1 Comparison of different production systems for expression of pharmaceutical compounds

	Production costs[a]	*Scale-up capacity*	*Humanization*	*Safety risk*	*Hurdles*	*Other considerations*
Bacteria	Low	High	None	Endotoxins		Currently in use for commercial production
Yeast	Medium	High	Incorrect			Currently in use for commercial production
Mammalian cell culture	High	Medium	Correct	Viruses; oncogenes		Currently in use for commercial production
Transgenic animals	High	High	Correct	Viruses/prions		Currently in use for commercial production
Plant cell cultures	Medium	Medium	Correct[b]	Low	Acceptance; regulatory	Single product in commercial production
Transgenic Plants	Low	Very high	Correct[b]	Low/ mycotoxins	Acceptance; regulatory framework	No products in commercial production

[a]Not including regulatory costs.
[b]Requires transgenic alteration of host plant. Without minor differences in glycosylation.

was the expression of human growth hormone in tobacco and sunflower callus tissue (Barta *et al.*, 1986). In this milestone example, human growth hormone messenger ribonucleic acid (mRNA) was correctly transcribed when expressed in the plant but not processed. Clearly, this was early in the demonstration of this technology, and active human growth hormone has since been produced from plants using a transient expression approach (Rabindran *et al.*, 2009).

Today, plant systems have been used to produce many types of therapeutic proteins, including collagen, interferon, and other replacement enzymes. As of this article, the farthest commercially advanced therapeutic, with Food and Drug Administration (FDA) approval, is manufactured by Protolix Biotherapeutics in a carrot cell culture system. The enzyme taliglucerase (Eleyso) is a therapeutic for treatment of Gaucher's disease, a lysozomal storage disorder, and has recently completed a phase-III trial (van Dussen *et al.*, 2012). Another therapeutic in late-stage development is a collagen product called Collage™, which has medical (wound healing) and possibly cosmetic applications. Produced by CollPlant in *Nicotiana tabacum*, production requires coexpression of five genes that are targeted to the plant vacuole (Stein *et al.*, 2009).

Vaccines

Vaccines are biological compounds that elicit immunogenic responses to diseases, primarily caused by microorganisms. In the context of PMPs, targeting second-generation vaccine products (subunits of a microorganism) have been attractive because the cell biology of plants is well suited for production of the glycoproteins or lipoproteins that typically constitute these antigenic molecules. Most interestingly, the plant tissue itself has been promoted as the delivery vehicle for vaccines by mucosal immunity (oral delivery) and this consideration drove initial development in the field of vaccine production.

An early example of vaccine production in plants is found in the patent literature (Curtiss and Cardineau, 1997), where the main claims concern immunity against pathogenic bacteria after oral delivery of transgenic tobacco leaves expressing bacterial antigens. A landmark paper establishing the utility of plants to express antigens involves expression of hepatitis B surface antigen (HBsAg) in tobacco plants (Mason *et al.*, 1992). Although shown to be biochemically equivalent to the human serum-derived HBsAg, demonstration of oral obtained immunity, knowledge of protein glycoslylation patterns, and increased total protein levels were demonstrated in subsequent studies.

A benefit touted in the early development of plant-produced vaccines was that production material, indeed the edible parts of plants, could be used as a delivery vehicle. This has an obvious public health advantage in developing countries where routine vaccinations can be difficult. However, as the technology has developed, problems with variable protein expression levels in the host plant and controlling the release kinetics of the vaccine result in an unpredictable dose, and these problems have guided the development of vaccines toward purification strategies and routes of administration that are parenteral (Obembe *et al.*, 2011). Additionally, although advances are being made in the understanding of the immunology of mucosally delivered vaccines, delivery of vaccines through injection is easier to test and better understood (Neutra and Kozlowski, 2006). Nevertheless, there is a recent example where reproducible and quantifiable levels of expressed protein are obtained from leaves that are dried and packaged into capsules. This is a promising approach to deliver a predictable dose (Lakshmi *et al.*, 2013).

A key milestone in the production of vaccines from plants occurred in 2006 with the first regulatory approval of a vaccine produced in plant cell culture; Newcastle disease vaccine is manufactured by Dow Agrosciences, LLC and is for veterinary use. The fact that it was produced in plants was the main advantage to this regulatory approval because contamination from animal proteins was not a concern (Vermij, 2006). Nevertheless, it has not been commercialized, as Dow had intended the approval as a case study in regulatory approval, rather than a step in establishing a platform. There are some industry examples of plant-produced vaccines currently in late-stage development. iBio, Inc. uses transient expression

technology of viral epitopes against H1N1 and H5N1 and has vaccines currently in Phase-I trials. Medicago uses a different technology, producing virus-like particles in leaf tissue, and has conducted clinical trials for H5N1 vaccine (Phase II) and H1N1 (Phase III) as well. Production of this vaccine is highlighted in the Section 'Case Study.' Clearly, production of second-generation-type vaccines today is feasible from both a technical and business perspective and vaccines for diseases such as cholera, rabies, and influenza are currently in efficacy trials.

Monoclonal Antibodies

As therapeutic proteins, monoclonal antibodies (MABs) are single-cell-originated proteins that bind foreign target molecules with high specificity to elicit various immune responses. Owing to their specificity, antibodies are used to treat diseases such as arthritis, immune and inflammatory diseases, or target-specific cancers for immune system recognition. Additionally, MABs are used for diagnostic purposes, disease prevention, and transplant rejection treatments (Fischer *et al.*, 2004). There are five types of antibody (immunoglobulin (Ig)) molecules produced by mammals (IgG, IgM, IgA, IgD, and IgE). Antibodies of the IgG, IgM, and IgA types are the most commonly expressed in plant pharmaceuticals, although other classes such as Fab genes (the variable, epitope-recognizing region of the antibody molecule) have also been successfully expressed. IgGs and IgMs are general classes of antibodies that play important roles in protecting the body from pathogenic infection (Knoll *et al.*, 2012).

Because glycosylation pathways and subcellular protein targeting and assembly are similar (but with important differences, see Section Purification) between plants and mammals, recombinant production of complex immunoglobulin molecules was predicted to be feasible. Indeed, the first report of antibody production in plants showed that a functional multimeric IgG could be isolated from a cross from separate *N. tabacum* plants stably transformed for the subunit chain components (Hiatt *et al.*, 1989). Importantly, assembly of this functional molecule required a secretion signal on both chains, highlighting the importance of correct subcellular targeting. Production of antibodies has now been demonstrated in plant species including Arabidopsis, carrot, potatoes, soybean, maize, alfalfa, and various tobacco species, among others. There are a variety of strategies for expression of these complex molecules that include a single transformation event (either stable or transient) from one transfer deoxyribonucleic acid (T-DNA) as well as utilization of specific subcellular targeting technologies to achieve efficacious glycosylation of the antibody (De Muynck *et al.*, 2010).

Several plant-produced antibody products have reached clinical testing stage. A product that prevents tooth decay, CaroRx™, has been tested by Planet Biotechnology. By binding to the bacteria *Streptococcus mutans*, this antibody keeps the bacteria from remaining on the teeth, preventing decay. Another example where pharmaceutical production in plants provides an advantage is the development of antibody microbicide directed at human immunodeficiency virus infection/acquired immunodeficiency syndrome (Lotter-Stark *et al.*, 2012). This promising therapy is closer to reality as Fraunhofer, IME, has successfully completed phase-I trials of an iteration of this therapy.

Production Systems

Plant biotechnology has successfully enabled the development of crops with new or improved attributes through ectopic expression (or suppression) of recombinant proteins, many of which have achieved commercial success. These include crops with quantitative changes in intrinsic properties, such as yield, tolerance to abiotic or biotic stresses, or qualitative changes in composition, such as accumulation of oils or with altered lipid profiles. The optimal expression of the recombinant protein is generally determined empirically by conducting phenotypic analysis, and often very low levels of the recombinant protein are needed to produce the desired trait without undesired off-types. In contrast, successful PMP production is largely a function of maximizing the protein yield, stability, and where necessary, posttranslational processing of the target protein. It is generally accepted that there is no reliable way of predicting a successful plant host, protein expression level, stability and assembly, and in the case of vaccines, whether the protein will be antigenic. Therefore, each of these aspects must be determined empirically. Although the range of available plant expression hosts for molecular farming is impressive, the choice becomes even more varied when the different expression systems are considered **Figure 1**. In this article, an expression host, an expression system, and production system are considered as separate entities: an expression host is defined as a particular species, whereas an expression system is defined as transformation and expression methods, including posttranslational strategies that address protein stability and efficacy. Production system describes the propagation and growth to harvest of the expression host. The combination of host and expression system results in an expression platform, for example, stably transformed rice seeds, transiently transformed alfalfa leaves, stably transformed tobacco suspension cells, virus-infected spinach leaves, etc. Factors that must be considered to guide the selection of the expression host and the assembly of the appropriate expression platform include the intrinsic properties of the protein; yield and scale-up requirements to meet expected market demands; speed of development of a new product; product quality criteria, such as correct protein folding and glycosylation, to 'humanize' the therapeutic; downstream processing and purity needs; delivery route; containment issues; and biosafety and regulatory considerations. For each of these factors, there are specific elements of the production platform that can be optimized (**Figure 2**). These elements will be discussed in the following paragraphs.

Expression Host

A broad range of plant species have been used for the production of therapeutics, including alfalfa, Arabidopsis, banana, barley, carrot, false flax, flax, lettuce, maize, pea, potato, safflower, spinach, soybean, tobacco, and tomato (Twyman *et al.*, 2013). Advantages of leafy crops, such as alfalfa and tobacco, include high biomass yield, multiple growth cycles per year,

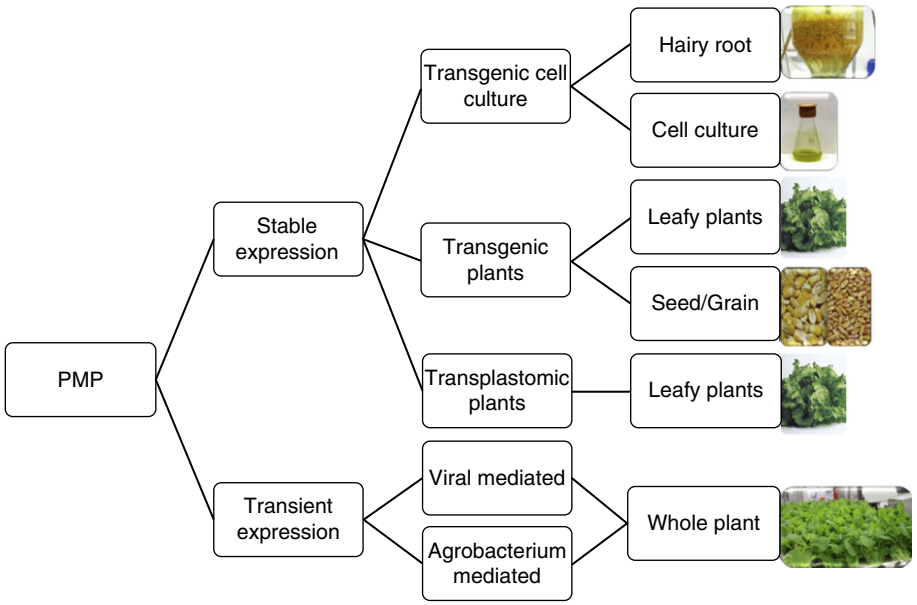

Figure 1 Representation of expression and production platforms for plant-produced pharmaceuticals.

	Host production system		
	Whole plants		Plant cell culture
Criteria	Stable transformation	Transient expression	Stable transformation
Speed of development	Long development time	Short development and production time	Short development and production time
Glycosylation	Similar to mammalian	Similar to mammalian	Similar to mammalian
Scalability	Highly scalable	Moderately scalable	Limited, costly

Figure 2 Comparison of key factors associated with different PMP production systems.

and established agricultural production practices. Tobacco has been the leading leaf-based system for commercial production of recombinant proteins since the first report of MAB-expressing tobacco (Hiatt *et al.*, 1989). The major advantages of tobacco are the well-established technology for gene transfer and expression, the high biomass yield (more than 100 000 kg ha^{-1} for close cropped tobacco because it can be harvested up to nine times a year), and the existence of large-scale infrastructure for processing that does not come into contact with the human or animal food chains. Nevertheless, because leaf tissue has high water content, proteins are expressed and accumulated in an aqueous environment where they are subject to degradation. Consequently, leaves must be processed soon after harvest, adding significantly to production costs. Although not as prolific as tobacco, alfalfa also produces large amounts of leaf biomass and has a high leaf protein content. Other leafy crops, such as lettuce, are being explored for PMPs. Because lettuce is edible, it may be possible to decrease or eliminate purification costs, if the leaf tissue is directly consumed.

The problem of protein instability in leaf tissue can be overcome by expressing proteins in the dry seeds of cereals and

grain legumes. Several different species have been investigated, including the cereals maize, rice, wheat, and barley and the legumes soybean and pea. Accumulation of protein in seeds and grain allows long-term storage of target proteins at ambient temperatures (Ramessar *et al.*, 2008). Scale-up capacity is high as seed yields can exceed hundreds of kilograms per hectare. Disadvantages of seed crops include the lower overall grain yields that are generally obtained relative to leaf biomass. Although there are specific examples where grain yields have exceeded that of tobacco (Stoger *et al.*, 2002), the biomass per hectare from a tobacco crop generally outweighs grain and seed.

Fruit and vegetable crops, like potato, carrot, tomato, and banana, have also been explored for PMPs and have the unique advantage of protein accumulation in edible storage organs; however, dosage from direct ingestion is not consistent, limiting their commercial development. Recombinant antibodies have been produced in potato (*Solanum tuberosum* L.) and tomato (*Solanum lycopersicum* L.), which also offer certain advantages over other crops. Proteins accumulating in potato tubers are generally stable because, like the cereal seed endosperm, these are storage organs that are adapted for high-level protein accumulation. The potential of potato tubers for antibody production was first demonstrated in 1998 (Artsaenko *et al.*, 1998) and have since been developed as a general production host for antibodies as well as other biopharmaceuticals based on antibodies (Schünmann *et al.*, 2002).

Production in plant tissues in cell-based culture systems has also been established and offers a higher degree of control for protein production than whole plant systems (Huang and McDonald, 2012). These plant cell culture-based bioreactor systems include suspended dedifferentiated plant cells, moss, and hairy roots. Compared with the use of whole plants or plant organs as a production platform, plant cell cultures offer several advantages for economical, sustained foreign protein production (Hellwig *et al.*, 2004), such as shorter production cycles (days or weeks); more consistency in batch-to-batch product yield, quality, and homogeneity of the target protein *N*-glycan pattern (De Muynck *et al.*, 2010; Liénard *et al.*, 2007); potentially cheaper and simpler downstream recovery and purification, particularly for products secreted into the extracellular medium (Rawel *et al.*, 2007); the elimination of the need for intensive labor for cultivation of greenhouse or field-grown plants; and the ease of compliance with cyclic good manufacturing practice (cGMP) requirements and product registration process, etc. (Huang and McDonald, 2012). Cell cultures have been derived from tobacco, rice, soybean, potato, and carrot that have successfully expressed therapeutic proteins and MABs, including enzyme taliglucerase (Eleyso) manufactured by Protolix Biotherapeutics in a carrot cell culture system. The scalability of bioreactor systems is limited relative to greenhouse or field production; however, the advantages can outweigh this for high-value compounds.

Expression Systems

The expression system encompasses the transformation system and the expression strategy, including posttranslational modifications (PTMs) of PMPs.

Transformation

Transformation refers to the process of delivering a recombinant DNA or RNA molecule to cells from which protein is produced, and the transformation system utilized will impact the outcome to at least as great an extent as host species. Transformation can be stable or transient. Stable transformation delivers DNA to either the nuclear or the plastid genomes, where the genetic material becomes integrated into the genome and becomes a stable part it. Efficient nuclear transformation systems have been developed for a broad range of crop plants. In brief, a DNA cassette containing the genetic code for the desired protein and instructions for the required spatial and temporal expression levels and patterns is introduced into the plant tissue either by direct means, for example, using biolistics, or via cocultivation of plant cells with transgenic *Agrobacterium* engineered to deliver the DNA expression cassette to the plant cells. Cells in which the transgenic material has successfully integrated into the nucleus are selectively cultured away from the surrounding nontransgenic cells, and using specific hormone regimes, transgenic plants are regenerated and sampled for protein expression. Plants containing the desired levels of the target protein can be grown to maturity and assessed for genetic quality and stability. Transgenic plant lines produced through stable transformation typically exhibit genetic stability over many generations, and accordingly, this plant production system is highly scalable. Nevertheless, there are disadvantages to stable transformation. Stable transformation is a time-consuming and costly process. The recovery of a single line with the required attributes can take several years. Low protein yield is the most common problem encountered using stable nuclear transformation, although optimization strategies exist to maximize protein yields.

An alternative to stable nuclear transformation is insertion of the coding material into the chloroplast genome, creating a so-called transplastomic plant. The presence of up to 100 chloroplasts in a leaf cell and up to 100 genomes per chloroplast allows very high protein accumulation. In one case, it was reported that levels of proinsulin accumulated between 47% and 53% of total leaf protein of transplastomic plants. With these protein yields, it is estimated that one acre of transplastomic tobacco could produce up to 20 million doses of insulin per day (Boyhan and Daniell, 2011). In another case, the human papillomavirus antigen was fused with an adjuvant and successfully expressed in transplastomic tobacco. This outcome paves the way for the development of low-cost adjuvant-coupled vaccines that may eventually obviate the need for cold chain and sterile needs (Waheed *et al.*, 2011). A summary of vaccine antigens against different human diseases expressed in plastids is presented in Lössl and Waheed (2011). This transformation system has some drawbacks. Because plastids lack glycosylation, this production system is suited only for non-glycosylated proteins, and the number of species for which efficient plastid transformation technology exists is very limited. Currently, tobacco and lettuce represent the higher plant species that have robust chloroplast transformation systems.

An alternative to stable transformation that overcomes many of the aforementioned limitations is transient expression. Transient expression enables rapid transgene expression and massive protein accumulation, often within days. For example, at the conclusion of a 30-day manufacturing

campaign, Medicago produced greater than 10 million doses of vaccine (see Section Case Study). Transient expression does not depend on chromosomal integration and is instantly scalable by increasing the number of host plants. There are two transient expressions systems in use: one based on plant viruses and the other uses the T-DNA from the bacterium *Agrobacterium*. For both, *Agrobacterium* is widely used as a delivery system. Viral vectors have attracted interest because in plants viral infections can be rapid and systemic and infected cells yield large amounts of virus and viral gene products (Streatfield, 2006). There are two major plant RNA virus expression vector systems engineered to express immunogenic peptides and proteins in plants. The first includes epitope presentation systems: short peptides fused to the viral coat protein and are displayed on the surface of assembled virus particles (virus lipid particles (VLPs)). The second class includes polypeptide expression systems where the proteins are not encapsulated after synthesis (Yusibov *et al.*, 2011). Plant viruses engineered to produce vaccines and therapeutic proteins include tobacco mosaic virus, potato virus X, cucumber mosaic virus, cowpea mosaic virus, and alfalfa mosaic virus. DNA viruses, specifically geminiviruses, have also been under exploration as protein expression platforms (Chen *et al.*, 2011).

In the agroinfiltration method, a suspension of recombinant *Agrobacterium tumefaciens* encoding the proteins that form VLPs or the therapeutic polypeptides on the T-DNA plasmid is infiltrated into leaf tissue. This initiates the transfer of the T-DNA to a very high percentage of cells, where the gene is expressed at high level for approximately 2–5 days without genome integration. Agroinfiltration allows for the routine production of 50–150 mg of protein per kilogram of leaf tissue in a timescale of weeks, and hundreds of kilogram of tobacco leaves can be processed in a single run.

Expression Methods

Although the intrinsic production capacity of the chosen production platform cannot be modified easily as it is dependent on the overall biomass yield of the crop, the specific yield of recombinant protein per unit of plant biomass can be influenced by the optimization of transgene expression, which is achieved through expression construct design. Gene expression is regulated at multiple levels in plants. In play are regulatory processes for transcription, translation, PTM, import and export, stability, and ultimately the degradation of proteins encoded by the nuclear or organellar genomes. Successful production of PMPs requires manipulating the regulatory machinery through the strategic use of endogenous and exogenous genetic and regulatory elements introduced into plant cells to orchestrate these processes to the desired ends (**Figure 3**). Perhaps the most important component of the expression construct is the promoter used to control transcription of the transgene. For dicotyledonous species, such as tobacco, potato, and tomato, the strong and constitutive cauliflower mosaic virus 35S promoter (CaMV 35S) is often chosen to drive transgene expression (Ma *et al.*, 2005). In cereals, other promoters have been tested, such as the maize ubiquitin-1 (ubi-1) promoter (Chiera *et al.*, 2007). Tissue-specific promoters are an alternative to constitutive promoters and can provide numerous advantages. For example, although constitutive promoters allow high-level accumulation of recombinant proteins in virtually all tissues, including meristems, leaves, pollen, seeds and roots, a seed-specific promoter largely restricts recombinant protein accumulation in the seeds, reducing or eliminating foreign protein accumulation in vegetative organs. In one case, yields in excess of 30% total soluble protein (TSP) of a single-chain antibody in *Arabidopsis thaliana* were obtained with the seed-specific promoter, arc5-I promoter from the common bean (*Phaseolus vulgaris* L.), and the antibody retained its antigen-binding affinity (De Jaeger *et al.*, 2002). There are other reasons to have an alternative strategy for promoter-driven localization of PMPs to different tissues. Although a high transcription level is desirable for maximal protein production, highly expressed transcripts and proteins may lead to growth and developmental defects in the plant or cell culture. Use of promoters that are conditionally induced may ameliorate this issue. A recent example is use of a CaMV 35S promoter that is engineered with control elements from the *Escherichia coli* tetracycline operon. This promoter is derepressed by the application of tetracycline and was shown to induce the expression of an antiinflammatory viral interleukin-10 (vIL-10) 3.5 times higher than with the standard CaMV 35S promoter (Bortesi *et al.*, 2012).

An appropriate polyadenylation site must be paired with any specific promoter and is inserted at the 3′ end of the coding region in the expression cassette (Ma *et al.*, 2003). With

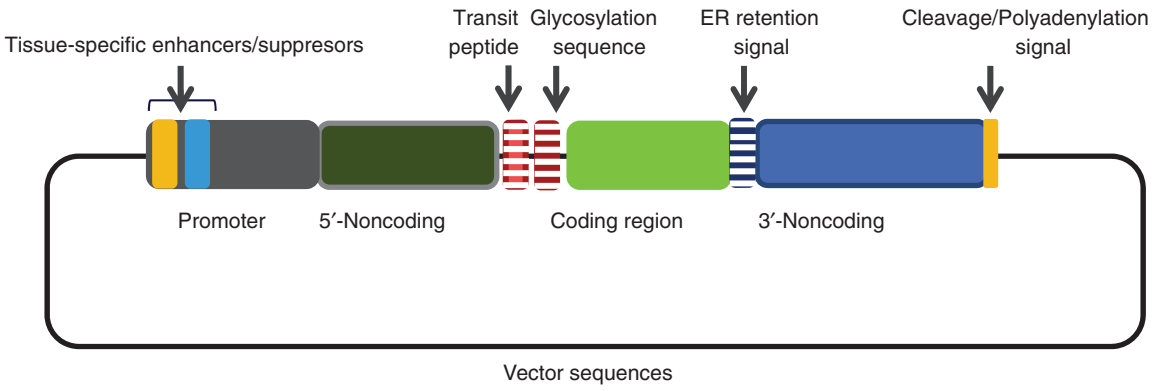

Figure 3 Representation of a plant expression vector, containing coding and noncoding elements necessary for protein production and posttranslational modifications.

the high expressing constitutive CaMV 35S or the maize ubiquitin-1 promoter, the polyadenylation sites of the CaMV 35S transcript, the *A. tumefaciens* nos gene, or the pea ssu gene are often used (Ma *et al.*, 2003; **Table 2**).

Posttranscriptionally, translational efficiency of the mRNA transcript can also have a profound impact on protein accumulation. One of the approaches to increase the translation efficiency in a given host is to optimize the codon usage in the mRNA, by changing the nucleotide (DNA) sequence without changing the amino acid sequence, to suit the respective host (Gustafsson *et al.*, 2004; Desai *et al.*, 2010). Preferred codon usage differs between monocots and dicots, and it is greatly different even between nucleus and plastid of the same plants (Desai *et al.*, 2010). Cryptic splice sites and sequences with the potential to form hairpins can also be removed from the construct (Gisby *et al.*, 2011).

There are many modifications a protein can undergo post-translationally, and early consideration of these in a PMP project is necessary to guide the strategy of expression and purification. PTMs include disulfide bond formation, hydroxylation, lipidation, and importantly, *N*-linked glycosylation. Disulfide bond formation improves protein stability in the cell, and during purification, hydroxylation and lipidation are frequently considered for product delivery, whereas appropriate *N*-linked glycosylation of PMPs is important for protein stability. These modifications are determined by subcellular targeting.

Therefore, after promoter choice and codon optimization, the next most important aspect of construct design is the inclusion of sequences that control subcellular targeting of the protein. This is another general method to increase the yield of recombinant proteins because the compartment in which a recombinant protein accumulates influences its folding, assembly, and PTM (Ma *et al.*, 2003; Schillberg *et al.*, 2005). Comparative targeting experiments have shown that the secretory pathway is a more suitable compartment for folding and assembly than the cytosol and is, therefore, advantageous for high-level protein accumulation (Schillberg *et al.*, 1999). Following the transcription and translation of a target gene, the recombinant proteins are directed to the secretory pathway using either a heterologous (part of the construct design) or an endogenous signal peptide located at the *N*-terminus of the nascent protein. Proteins containing these targeting signals are cotranslationally imported into the endoplasmic reticulum (ER) and are eventually secreted into the apoplast, a supracellular network of interlinked compartments underlying the cell wall. Depending on its size, a protein can be retained in the cell wall matrix or can leach from the cell. This 'default' pathway for proteins in the secretory pathway allows apoplastic localization of a PMP and can be a useful approach for protein purification from root cultures or in single-cell systems such as algae (Nagels *et al.*, 2012).

Some peptide signals required for targeting through the endomembrane system and to specific organelles are well known, such as ER retention peptide, whereas others, such as vacuole-targeting signals, have not been shown to have a canonical sequence and need to be empirically determined (Vitale and Pedrazzini, 2005). Once known, these signals are easily engineered onto the protein. Because the majority of recombinant proteins are most stable in the ER lumen, an effective strategy in increasing protein expression levels is to confine the protein to the ER using an H/KDEL C-terminal tetrapeptide 'tag,' in addition to the signal sequence. Accumulation levels can be increased up to 100 fold by adding the KDEL signal (Schillberg *et al.*, 2002). A further advantage of ER accumulation is that these proteins will not be modified in the Golgi apparatus (GA), preventing modification with plant-specific xylose and fucose residues (Sriraman *et al.*, 2004). In addition, the ER provides an oxidizing environment and an abundance of molecular chaperones; however, the number of proteases is only a few.

Table 2 Examples of Promoter and Tissue Localization of plant-made pharmaceuticals (PMPs) in development

Protein	*Tissue*	*Plant species*	*Promoter*	*Subcellular localization*	*Production level*
Cytokinin viral interleukin-10	Cell culture	Tobacco	Inducible: Tetracycline derepressed		9.3±1.4 μg g^{-1} fresh weight
Taliglucerase	Cell culture	Carrot			
B-subunit of the heat-labile toxin	Hairy root	*Nicotiana tabacum*	NtQPT2: wound-inducible root localized		330 μg g^{-1} fresh weight
H1N1	Leaf	*Nicotiana benthemenia*	CaMV 35S	Lipid rafts of plasma membrane	200 μg g^{-1} fresh weight
HBsAg	Tuber	Potato	CaMV 35S+PB33 (patatin)		1 μg g^{-1}
Human transferrin	Seed	Rice	rice seed storage protein glutelin 1 gene promoter	Endomembrane system	8–10 mg g^{-1} seed weight
Human insulin-like growth factor 1 (hIGF-1)	Seed	Arabidopsis	Oleosin promoter	Oil bodies	0.17% of the TSP
Human immunodeficiency virus protein Nef	Leaf	Tobacco	cauliflower mosaic virus 35S (CaMV 35S)	Endoplasmic reticulum stacks	0.7% TSP
a1-Antichymotrypsin protein	Leaf	Potato	CaMV 35S with coexpressed protease inhibitor	Cytosol	Threefold higher than without inhibitor

Protein storage vacuoles are important organelles of the endomembrane in the seed, and targeting recombinant proteins to these organelles permits seed localization, resulting in the aforementioned advantages of high stability and storage capability.

In addition to the secretion pathway, there are other ways to utilize the endomembrane system for enhanced protein stability. For example, because the first step in protein glycosylation occurs in the ER in some cases, adding sugar moieties to a PMP may not be desired. Glycosylation can be avoided at this step by targeting oil bodies. These organelles derive from the ER membrane; although the localization signal is embedded in the membrane, the C and N termini of the protein are exposed to the cytosol. This strategy was used for both the thrombin inhibitor hirudin in oilseed rape (Obembe *et al.*, 2011) and insulin in *Arabidopsis* seed (Li *et al.*, 2011). Another novel approach to avoid glycosylation in the ER lumen yet retain stability in the cytosol leverages the C-terminal of tail-anchored membrane proteins on the ER. As an example of this system, the human immunodeficiency virus protein Nef was anchored to the cytosolic face of the ER membrane by fusing to the C-terminal domain of mammalian ER cytochrome b5, a tail-anchored (TA) protein. This resulted in a stacked ER structure that protected the protein in the cytosol. The recombinant protein Nef could be removed *in vitro* from its TA because a thrombin cleavage site had been engineered between the protein and the anchor (Barbante *et al.*, 2008).

To avoid unwanted PTM on a PMP, expression outside of the endomembrane system in the cytosol can still be a viable option. Stable protein expression can be achieved but generally requires the presence of recombinant protease inhibitors. The PMP can be coexpressed with a cytosolic protease inhibitor, such as tomato cathepsin D inhibitor (Goulet *et al.*, 2012). In this example, the authors show not only the increased protein levels in leaf tissue but also increased stability of a human a1-antichymotrypsin protein in the presence of this inhibitor.

Humanization via posttranslational modification

Humanization of therapeutics refers to the PTMs of a PMP to closely resemble the same protein had it been produced in human cells. The primary modification of concern is *N*-linked glycosylation and is important because of the roles that glycan structures play in immune recognition.

The process of *N*-linked glycosylation involves sequential addition and trimming of sugar chains (glycans) onto a nascent secretory protein as it moves through that pathway. These sugar modifications on the resulting glycoprotein are important for protein stability, activity, trafficking, and targeting, as well as pharmacokinetic properties of protein therapeutics. For example, protein stability is driven by the high mannose glycan structures that initially decorate proteins because these are ligands for the ER-based calnexin/calreticulin protein-folding checkpoint. Beyond roles in protein stability, glycans can also be key efficacious aspects of a therapeutic. For example, a well-characterized mammalian-targeting signal glycan is phosphorylated $Man_8GlcNAc_2$ structures found on protein hydrolases; the mannose-6-phosphate receptor in the *trans*-Golgi-network (TGN) recognizes that structure on the hydrolases to import them into the lysosomes. Loss of these protein hydrolases is the basis of many lysosomal storage diseases, so these proteins are key pharmaceutical targets. From a pharmacologic perspective, glycoproteins also serve as potent recognition ligands for macrophage-located receptors in order to elicit an efficient immune response (Nagels *et al.*, 2012).

The *N*-linked glycosylation pathway is an active area of study in plants and excellent detailed reviews on the topic are available (e.g., Ruiz-May *et al.*, 2012; Gomord *et al.*, 2010). A brief summary is useful to illustrate some important differences between plant and animal glycosylation pathways. The first step in protein glycosylation is the attachment of a cytosolic and ER lumen-generated high mannose sugar ($Glc_3Man_9GlcNAc_2$) oligosaccharide core structure select asparagine (Asn) residues. The Asn residue is embedded in the consensus sequence *N*-X-(S/T), where X is any amino acid but proline. This step occurs in the ER lumen and is conserved among eukaryotes. Additional saccharide trimming and important glycoprotein-folding checkpoints (e.g., the calnexin/calreticulin pathway) occur in the ER before the glycoprotein moves to the GA. *N*-acetylglucosamine molecules are added to the sugar chain and the mannose core is trimmed in the initial part of the GA. The trimming and subsequent glycan additions occurring beyond the ER result in moieties referred to as complex *N*-glycans. The pathways between plants and humans then diverge as the glycosylated protein sequentially moves past the *cis*-Golgi further into the GA (**Figure 4**). Past the *cis*-Golgi, the plant-specific β1,2-xylose and core α1,3-fucose sugar molecules are added to the core $Man_3GlcNAc_2$ molecule. Additional maturation to these plant glycan structures in some tissues include the so-called Lewis (Le^a) epitope, where one or two β 1,3-Galactose, α 1,4-fructose moieties are added onto the last GlcNAc residue. This antennae structure is thought to elicit an IgE-mediated immune response. Indeed, generation of complex glycans can be different even between plant species and organs. For example, in monocot seeds, Le^a-antennae are not added. Hence, consideration of glycosylation differences between species can also drive species decisions for PMP development. Subsequent to processing in the GA, glycosylated proteins are sorted in the TGN to their final destination at the plant cell wall, apoplast, vacuole, or chloroplast.

Owing to the importance of glycan structures for therapeutic efficacy and the potential for immune reactions to plant glycan structures, platforms for the 'humanization' of PMPs have been developed. In one such platform, the Golgi additions can be avoided by targeting the PMP to remain in the ER by means of the ER retention signal (C-terminal K/HDEL). An interesting additional use of this platform is primarily the exploitation of the oligomannose glycan structures decorating the protein in this compartment. The mannose glycan structure on proteins is detected by mannose receptors on macrophages, and this approach has been used to target therapeutics that address lysosomal storage disorders. In another humanization platform, the plant-specific β1,2-xylose and core α1,3-fucose glycosyl transferase genes can be knocked out using RNAi technology, minimizing the glycan elaboration with these plant-specific structures. In a third approach, human glycosyl transferases are engineered into the host plant. In this platform, the recombinant transferases are preferentially used in Golgi-located galactosyl additions (Webster and

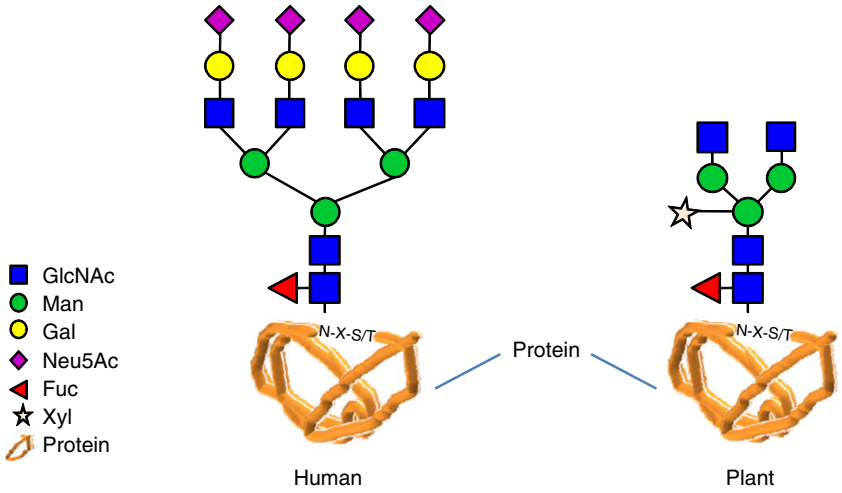

Figure 4 Some key similarities and differences of complex human and plant glycosylation. Note the xylose present on the plant structure, not present in human structure, and the sialic acid structure at the terminal of the human structure. Structures are elaborated according to Consortium of Functional Glycomics essential symbols nomenclature: http://www.functionalglycomics.org/static/consortium/Nomenclature.shtml

Thomas, 2012). Finally, a recent report highlights the successful addition of terminal sialic acid residues onto plant-produced glycoproteins by introducing the human pathway into *Nicotiana benthamiana* (Castilho *et al.*, 2010).

Another PTM with therapeutic consequences is O-glycosylation. In O-glycosylation, fucose, xylose, mannose, GlcNAc, galactose, glucose, or *N*-acetylgalactosamine (GalNAc) residues are added to the hydroxyl group of serine or threonine on proteins that have completed their folding in the GA. In mucin-type O-glycosylation, additional sugars are then added to these structures. The resultant modification affects biological activity of proteins involved in inflammation response, coagulation, cancer, and viral infection pathways. Unlike *N*-linked glycosylation, the O-linked pathway in plants is not as well described as in mammalian systems; although monosaccharides are added to proline, hydroxyproline, and serine in plants, mammalian-like additions (e.g., GlcNac) have just recently been described (Gomord *et al.*, 2010). In biopharming, O-glycosylation has primarily been used to stabilize proteins to increase their shelf life by adding an O-glycosylation consensus sequence to the C-terminus of the protein (Webster and Thomas, 2012).

Hydroxylation of proline on proteins is a PTM that affects stability in some proteins; collagen is an example. The hydroxyproline modification has been characterized in plants at only low levels; consequently, a humanization approach has been used to recapitulate this modification in plants. Coexpression of collagen and recombinant prolyl 4-hydroxylase in transgenic maize seeds has been shown to produce effective levels of hydroxyproline-stabilized collagen (Xu *et al.*, 2011). This modification has been used more to improve stability and shelf life of the protein rather than address its immunological effect (Webster and Thomas, 2012).

The addition of lipid molecules onto proteins (e.g., palmitoylation and myristoylation) is a PTM that has been considered in PMP design. Lipidation serves primarily to target the protein on the plasma membrane or other intracellular lipid location and also has been shown to have roles in signal transduction. Correct subcellular targeting of PMPs that require lipidation is important; lipidation of the OspA vaccine against Lyme disease or the Nef12 protein that addresses the immune response to HIV indicates that chloroplast targeting is a key to developing efficacious proteins (Webster and Thomas, 2012).

Production System

Production refers to the method of propagating, growing, or producing plant, organs, or cells from which the PMP will be purified. To a great extent, the host organism and expression strategy will dictate the production method. For example, expression of a recombinant protein in seeds requires field production of stably transformed whole plants. Leaf expression can be achieved in field or protected culture and be the product of stable, transient, or plastid transformation methods. Because the production method has significant implications for cost, scale-up, and risk management, it needs to be factored early in the process. The regulatory framework for genetically modified organism crops is presented elsewhere in this volume, and regulatory considerations for PMP are discussed in the Section Regulatory Considerations; hence, they will not be addressed in this section. Where production method as it factors into the key decisions for PMP production will be reviewed.

There are essentially five options for PMP production. These are: growth of whole stably transformed plants in open fields; growth of whole stably or transiently transformed plants in a greenhouse; growth of whole stably or transiently transformed plants in an artificially lit growth chamber; production of lower or aquatic plants in a semiclosed system; and production of plant cells in a sterile, closed bioreactor (**Table 3**). Growth in open fields theoretically allows infinite scale-up, limited only by the amount of seed produced to establish the crop. Indeed, perennial crops, such as alfalfa, can even allow multiyear production. Field production provides the greatest flexibility for production platforms, as it encompasses the

Table 3 Comparison of production systems for plant-made pharmaceuticals (PMP)

Production system	*Type of plant*	*Advantages/challenges*	*Example*
Closed system	Single-cell suspension, hairy roots, or anchorage dependent cells	• High level of containment • High level of control • Cell seed stock well characterized • Bioreactor based • Expensive to implement	Protalix Biotherapeutics Carrot cell culture Taliglucerase alfa
Semiclosed system	Small aquatic plants that can be grown in sterile cell culture	• High level of containment • High level of control • Single-use systems with overhead lighting • Expensive to implement	Biolex/synthon Lemna Interferon alpha 2b
Enclosed artificially lit chambers	Tobacco, lettuce, tomatoes, alfalfa, etc.	• Light cycle, temperature, humidity, and CO_2 control • Automatable • Expensive utilities • Transient expression possible	Fraunhofer Nicotiana Flu HA protein
Greenhouse	Tobacco, lettuce, tomatoes, alfalfa, etc.	• Sun supplies energy • Supplemental light required to supplement seasonal affects • Transient expression possible • Automatable • Inexpensive	Medicago Nicotiana Flu virus-like particles
Field	Tobacco, lettuce, tomatoes, alfalfa, potatoes, bananas, etc.	• Sun supplies energy • Containment difficult • No barrier to pests • Transmission through animals and birds	Prodigene Corn Trypsin

broadest number of host species and expression systems. Field-based production also does not require a capital-intensive infrastructure. Nevertheless, there are significant drawbacks that have to date limited the number of PMPs produced in open fields. As mentioned in the Section Transformation, the development of stably transformed transgenic or transplastomic crop lines for commercial production requires many years and millions of dollars in development costs, making this potentially the highest cost production method. In addition, regulatory agencies, such as the United States Department of Agriculture (USDA), impose more stringent regulations than what is required for transgenic plants expressing nontherapeutic proteins. The primary difference for PMPs over the so-called input traits for genetically engineered crops entails the level of containment required when a crop expressing an output trait, such as PMP, is in the field. For example, fields are subject to multiple inspections, the field must be surrounded by a 50-foot fallow zone, isolation distance from similar crops is strictly enforced with wind-pollinated crops at a larger distance than self-pollinated crops, and equipment must be dedicated to the field trial for the entire field season and then cleaned using the USDA-approved Standard Operating Procedures. No crop can be planted on the plot the following year, so that volunteers can be destroyed. These requirements increase production costs over other types of transgenic crops (Breyer, 2009). For a list of crops for which field trial permits have been obtained and case studies for field release of PMP, see Breyer *et al.* (2012). A recent survey of farmer's perceptions of biopharming showed that the greater the number and cost of production changes, the fewer the farmers were willing to adopt the technology, even if profits increased (Hayes and Kostandini, 2013). An evolving, but yet not finalized, process for GMP for field-based production increases substantially the uncertainties of field production.

Growth in enclosed or protected environments, such as greenhouses and growth chambers, has been widely adopted for PMP, including vaccines, monoclonal antibodies (MABs), and therapeutic proteins, for a variety of reasons, such as providing physical containment and confinement. Scale-up is limited by facility size, whereas production can continue year-round with multiple production runs possible annually. Potato and a number of leafy crops, such as tobacco, alfalfa, lettuce, and spinach, are examples of plants that can be grown successfully in contained facilities. All can be stably transformed and for lettuce and tobacco, plastid transformation systems have been developed. For a stably transformed line, a master stock of transgenic seed (or asexually propagated tubers in the case of potato) is produced that is planted to initiate a 'run.' Maximum flexibility is achieved when transient expression is used as the expression system. Although transient expression systems exist for multiple plant species, *N. benthamiana* is used almost exclusively for commercial scale transient production, having the most well-developed system, including multiple vectors (Hellens *et al.*, 2005) and silencing suppressors (Voinnet *et al.*, 2003).

Plant cell culture techniques have been in existence since the 1950s and have been utilized successfully to synthesize a wide variety of natural compounds with therapeutic value, including paclitaxel (Taxol). Recombinant therapeutic protein was produced in tobacco cells in 1990, and since then, a number of antibodies, enzymes, hormones, and growth factors have been produced (Hellwig *et al.*, 2004; Paul and Ma, 2011). Plant cell cultures combine the advantages of whole plant

production with those of microbial cultures (Huang and McDonald, 2012). Growth in a bioreactor allows precise control and batch-to-batch consistency and enables GMP production practices. Several approaches can be used for the *in vitro* production of plant cells, but the two systems widely used for PMP are cell suspensions and hairy root cultures. (Bioreactors can also be used to culture aquatic plants, moss, and some algae, for PMP production, and that will not be covered here.) Recombinant suspension cultures have been derived from several species, including *Arabidopsis*, tobacco, rice, soybean, tomato, and carrot. To establish a cell culture for PMP, a transgenic plant or transgenic cell line is produced and selected for stable, high-performing cell lines. These master lines are then scaled up for production. Hairy roots are generated by infection of plants with *Agrobacterium rhizogenes* that contains the 'root-inducing' (Ri) plasmid. Integration of the plasmid into the plant genome results in differentiation and growth of neoplastic root structures called hairy roots. Once established, hairy root cultures grow rapidly and can be propagated indefinitely in liquid medium. The number of species reported to have successfully produced therapeutics via hairy roots is limited and includes potato and tobacco (Huang and McDonald, 2012). The morphology and culture characteristics of hairy root cultures are different than suspension cultures and can create unique challenges that have to be taken into account (Huang and McDonald, 2012).

Purification

Biotherapeutics are typically administered by injection, although oral administration of plant-produced vaccines has been suggested and studied. In the case of injection, the product typically is of a higher purity than a product that is administered orally. Removal of host cell proteins, DNA, vector (virus or *Agrobacterium*), and other plant-based compounds such as chlorophyll and nicotine during processing is a necessity in injected products, whereas in an oral pharmaceutical, the presence of some of these compounds would be fully acceptable.

Production of an injectable product requires an extensive amount of purification. A purification process may be divided into three general stages: product recovery, clarification, and purification. Plant-based therapeutics use purification strategies common to other biologics (Li and Qiu, 2013). These include chromatographic operations as well as multiple types of filtration operations. These types of operations are well documented in many reviews (Li and Qiu, 2013) and any number of commercial suppliers of chromatography resins and filtration media and equipment are willing to aid in development of these purification operations. An example of techniques used in downstream purification of a plant-derived vaccine is given in the 'Case Study' at the end of this article.

However, plants, when used as hosts for protein production, present unique challenges to bioprocessing recovery and clarification operations. Plants contain a large amount of fibrous, solid material that is a barrier to recovery of therapeutic molecules, especially protein. Thus, recovery operations for plant-based products often include a milling, grinding, pressing, or digestion step that is more severe than steps used in some microbial or mammalian cell culture operations. If the product of interest is prone to physical degradation, these operations may have a detrimental effect on product quality. Elimination of these solids in the food and beverage industry is often part of production processes and thus methods of production may be adapted from these industries. However, the standards for equipment design and cleaning are often more strict in the pharmaceutical industry as compared with the food industry and thus specialized equipment may need to be designed.

Some plants contain low molecular weight compounds that are subject to rapid oxidation and are capable of impacting coexisting proteins in the early-process stream. The time required to separate these compounds from the target protein and the methods used to prevent oxidation have a major impact on product quality. Attention must be given early in a plant-based process to a wide variety of compounds, such as chlorophyll, phenolics, and alkaloids, that are not present in microbial and mammalian cell-based processes.

Colored components, such as chlorophyll, are easily visible as process residues in equipment used in plant-based processes and present a challenge in removal from the process stream as well as in equipment cleaning. The presence of pectins, cellulose fibers, and other viscous, slime-like residues are a challenge to clean from processing equipment, such as centrifuges, filter housings, and mixing vessels. The selection of proper cleaning agents is critical in validation of cleaning operations in plant-based processes. The presence of these viscous components in a process stream also creates challenges in mixing, fluid movement, and product recovery in the production process.

Production of an orally available biotherapeutic may require minimal or no purification. A transgenic plant that is edible is in itself a potential product if the biotherapeutic can survive the transport to the site of interaction (typically the gut). However, use of a system such as cell culture or a transiently infected plant that is not typically part of the food chain would require at least partial processing and formulation to make the product not distasteful to the patient. Removal of objectionable species in some production systems, such as very high bioburden levels in *Agrobacterium*-infiltrated systems, may be required and would depend on the production system. Orally available biotherapeutic products may be viewed as more akin to food than drugs from a safety perspective; therefore, many process controls that exist in the pharmaceutical industry would likely be relaxed and the manufacturer could argue that compliance with the food industry's regulations was sufficient. However, the burden of proof of product stability, process reproducibility, and efficacy would still fall on the manufacturer and adherence to pharmaceutical requirements in these areas would more likely apply.

Regulatory Considerations

The use of plants as the 'biofactories' for making a protein-based pharmaceutical requires a new level of consideration of the risks associated with the plant and production process as compared with those used for food or even medicinal small-molecule products. Consideration and ranking of the risks will

initially depend on the route of administration of the product produced, the population that will receive the treatment, and existing therapies for the disease target (e.g., does the new product provide a solution for an unmet clinical need?). As always, there are no templates one can use that guarantee success in regulatory acceptance, and each country's regulatory agency has unique concerns about the production of biopharmaceuticals. The sponsor of a new entity produced in plants will more likely have their product considered by the regulators on a 'case-by-case' situation.

The regulatory considerations begin with the choice of the plant host system that will be used to produce the protein therapeutic. The increased genetic knowledge and ability to manipulate protein expression of many systems has led to opportunities to use single-cell systems as well as whole plants or fungi. If an edible plant is chosen as the production system, it will be important for the manufacturer to assure regulatory agencies that there are tight controls around the biomass that would prevent its unwanted entry into the food chain. If the system is edible and also transgenic, cross-pollination with other food source plants in the surrounding area is of concern, so the containment used to grow transgenic plants that produce a biotherapeutic protein must also be considered and demonstrated. Examples of the many plant types that have been considered and containment considerations are shown in **Tables 2** and **3**.

One factor that requires attention and greatly affects the process and facility design is containment of the plant during its growth. A diverse range of options are available to consider here. ELELYSO™ or taliglucerase alfa (Protalix Biotherapeutics), an approved drug for Gaucher's disease, is produced using a carrot cell culture system that can be tightly controlled and operated as a closed system. In contrast, consider the other extreme case of a crop grown in a field in a developing nation in order to provide low-cost injectable vaccines to a large population. The level of control around plants is completely different in these two cases and must be considered in the manufacturing process.

A case where product from a genetically modified corn crop was mixed with a soybean crop harvested for food after use of the same field for growth led to large fines and even larger cleanup costs in 2002 in the US. This led to a major setback in the consideration of using a field-based crop system in the US. **Table 3** lists some of the considerations for containment of the production system chosen.

In theory, it is possible to use field-grown plants for manufacture of a product for injection. However, at the current time, the lack of regulatory experience with plant-based pharmaceuticals in the USA, Canada, and Europe may result in a barrier to entry that is too high to attempt to push this system through toward product licensure.

The theoretical risk of adventitious agent (AA) entry into the product in an open processing system (plant growth through extraction of the protein of interest) will always be present and there is no way to effectively argue against a theoretical risk. Therefore, a large burden will be placed on the production process to provide assurance that any potential threat would be eliminated. For the first generations of plant-produced biotherapeutics, the use of a contained environment, such as a greenhouse or growth chamber, is more likely to be the minimal requirement for use in the growth of plants and will be considered in the following sections. However, a recent draft Health Canada Guidance, human-use biologic drugs derived from plant molecular farming (PMF), proposes that it is acceptable to use a field-based crop to manufacture PMP if the proper controls are in place. The FDA has published a Guidance for Industry, "Drugs, biologics and medical devices derived from bioengineered plants for use in humans and animals," which is useful in developing strategies in navigating the regulatory pathway in the US. Based on these guidance, the case can be made that plants used in the production process are a critical raw material that can be produced under controlled 'GMP-like' conditions as opposed to more traditional organisms grown in fermentors or bioreactors that are considered as a part of the manufacturing process from the moment they are used to establish a master cell bank.

After the plant and growth system are selected, the next level of critical decisions must be made by the manufacturer. If a whole plant system is chosen, a selection must be made on the substrate to support the plant. A synthetic system, such as rock wool or Pillowtex, may be chosen or a natural substrate, such as soil or peat, may be used. The design of the facility will depend on this choice as the robotics to manipulate the different systems must be considered. In addition, the substrate chosen impacts the control required around feeding, control of microorganisms, and waste management. The value of the product (e.g., a flu vaccine that sells for US$30 or a cancer treatment that may sell for thousands of dollars a dose) and the process yields, production costs, and development costs will impact some decisions in the choices made. For instance, a greenhouse that uses the sun's energy to provide light may have lower operating costs as compared with a closed system lit entirely by artificial lights. However, the process control and biomass productivity may be more consistent in an artificially lit system (Wirz *et al.*, 2012). Consideration on how the plants will be manipulated must also be made early in the process design phase. Robotics has great potential to minimize human–plant interaction and is operationally efficient but requires high capital investment. Manufacturing personnel can be used in the process of growing and moving plants and are very adaptable but create a concern for introducing AAs in the process as will be discussed further in the Section Case Study. The choice of the system will more likely depend on what product is being produced and labor costs figure into the location of the production plant.

In the past, plant-based systems used for production of biotherapeutics were often described as extremely safe in the literature and hence it had been suggested that there is no AA risk in products produced in plants (Fischer *et al.*, 2012). Although it is true that the risk of AA derived from a plant cell is much less than that in a product derived from a mammalian cell, regulatory agencies do not consider the risk zero. Concern that an AA which could jump species from plants to humans may appear in the future or that an AA which had not been detected (i.e., porcine circovirus in Merck's and GSK's rotavirus vaccine (Victoria *et al.*, 2010)) may emerge in a product is of regulatory concern in all countries. Therefore, any plant-based manufacturer can be certain that they will be asked to show at least some viral inactivation or clearance in their process. The main concern will be introduction of AA from human sources,

for example, people interacting with process intermediates; rodents in the facility or in contact with raw materials; especially hard to control in field-grown crops; or insect- and animal-derived raw materials used in the process. Knowing this, a manufacturer can choose production methods to mitigate risks, provide viral clearance in their production process, and choose raw materials that carry a low risk of introducing any AA into the process. A detailed guidance on AA considerations may be found on the FDA website in document ICH Q5A (R1).

Control of bioburden, including mycoplasma and spiroplasma, is also important in production processes. Bioburden can often be removed early in purification operations by the use of a sterilizing grade filter. However, bioburden alone is not the only agent that may contribute to safety concerns in a biopharmaceutical. Contaminants, such as mycotoxin (from fungi) and endotoxin (from Gram-negative bacteria), must also be excluded or removed from process intermediates before producing drug product. Exclusion of endotoxin becomes a challenge when *Agrobacterium* is used as the transfer vector for genetic elements in a process, because it is a Gram-negative bacterium that releases endotoxin into the production stream. Control of bioburden and other contaminants in raw materials must also be considered and critical raw materials must be tested and limits set as to the appropriate level of contaminants that a raw material may contain and that the production process can tolerate.

As with the production of any biopharmaceutical, the production process must adhere to current GMP practices. It is up to the manufacturer to design a facility and production process and use materials that comply with the Code of Federal Regulations, Title 21. The interpretation of what constitutes the production process, where it begins, and how plants can be considered a critical raw material in the process is the manufacturer's case to make. Reference to the Guidance for Industry Q7A, Good Manufacturing Practice Guidance for Active Pharmaceutical Ingredients, is useful in this respect. Nevertheless, the regulatory agencies must concur with the proposal if regulatory approval for the product is to be granted and control over the growth and acceptability of plants as the 'bioreactor' for a biotherapeutic is mandatory. Thus, even a plant-based production process must comply with industry standards in terms of facility and process validation, including cleaning and changeover between production campaigns; people, material, and waste flow in the facility; segregation of raw materials, process intermediate, and product; and adequate documentation, including testing, production records, and change of control management.

In summary, there are many considerations to be made in the selection of a host plant, process, and facility to be used in the manufacture of a biotherapeutic. The best decisions are made by assembling a diverse team of scientists, engineers, and quality and regulatory subject matter experts, so that many aspects of the product and its manufacture are considered. Failure to adequately consider many factors can result in product failure, as the product development evolves and much money has been committed to development. This topic has been considered by many academic and industrial subject matter experts and reviews (Sparrow *et al.*, 2007) are available for those wishing to explore this topic in greater detail.

Case Study

Case Study: Rapid Production of Vaccine in Plants to Address Pandemic Threats

In 2010, Medicago was contacted by the Defense Advanced Research Projects Agency (DARPA) to partner in a program sponsored by the US government to prevent strategic surprise from negatively impacting the US national security and create strategic surprise for the US adversaries by maintaining the technological superiority of the US military (DARPA Website). Medicago was asked to demonstrate the potential of a plant-based biopharmaceutical vaccine to mitigate risks associated with a pandemic threat because of the speed and flexibility with which a new vaccine could be produced by Medicago. This request was also made because Medicago had clinical experience with plant-based, highly immunogenic vaccines that contained flu hemagglutinin (HA) proteins in virus-like particles. To accomplish the key milestones of the project, Medicago had to build a facility, scale up, and transfer a vaccine production process in approximately 1 year and then produce 10 000 000 doses of a flu vaccine in 30 calendar days. The following case study highlights the process used to produce the vaccine.

The production of the vaccine can be divided into three main sections: (1) transient protein expression after *Agrobacterium* delivery to leaf tissue, (2) protein separation from plant biomass via tissue digestion, and (3) protein purification via standard industrial filtration and chromatographic techniques.

Production: Host Plants

Nicotiana benthamiana was selected as the host system because it had been demonstrated to be efficient at transient expression of a variety of proteins, it was an efficient system for infiltration and, its natural protease profile was lower than many other species. The growth environment chosen for *N. benthamiana* was a greenhouse. This system was selected on the basis of a number of factors, including cost of greenhouse construction, cost of producing plants in this environment, energy use, simplicity, and previous experience with growth and protein expression in *N. benthamiana*. Each production lot was initiated with seeding to paper pots and seedling germination within a growth chamber. After germination, plug trays containing seedlings were moved into the greenhouse. Once the seedlings reached the appropriate stage of growth, they were transplanted into pots containing peat-based substrate and automatically moved back into the greenhouse via a rail and drive system for further growth. Pots were rearranged from a high- to low-density configuration after growth in the greenhouse for a predefined period. This respacing was accomplished using robotics to pick and replace the pots onto greenhouse tables. The robot is shown in Figure 5. The plants were monitored for stage of growth, physical characteristics, absence of disease, insect contact, and soil chemistry throughout the growth cycle. Watering and fertilization were accomplished automatically with a flood and drain type system that was able to deliver fertilizer of desired nutrient content depending on stage of growth of the plants. The greenhouse area required for

Figure 5 The pick and place robot used for plant arrangement for greenhouse operations.

Figure 6 Infiltration robot used to introduce *Agrobacterium* into the leaf tissue of plants.

expansion of biomass was determined on the basis of the number of plants required to meet the production objectives, the level of protein expression in the plants, the process recovery, and the dose to be administered. Given the objective of the DARPA project to produce 10 000 000 doses in 30 days, the greenhouse- and plant-handling operations occupied approximately one third of the total production facility space. After the manufacturing campaign was completed, the data generated from growth of plants indicated that the greenhouse system was of sufficient size, was efficient, and resulted in production of healthy plants that were of a consistent growth stage and target weight (±13%). A video clip of the greenhouse operations is available at LLL.

Production: Expression System

The expression system used for the H1 protein and VLP production was based on *Agrobacterium* transfer of genetic material to plant cells in the leaf tissue of plants. Medicago used a binary plasmid to develop its genetic construct. A binary plasmid is a plasmid that can multiply (replicate) in two hosts. For the molecular work involved in the assembly of genetic constructs, the host used was *E. coli*. The binary plasmid consisted of regions responsible for replication in the two hosts (*E. coli* and *A. tumefaciens*) and of regions located within T-DNA borders. Expression cassettes consisted of assemblies of DNA transcription and translation elements, one of which was the gene encoding the H1 protein. When genetic constructs were completed, the resulting plasmid was transferred to *Agrobacterium*. *Agrobacterium* was the 'transfer' vector used to pass the genetic information into plant cells. Medicago's expression system required the use of a suppressor of silencing as a helper protein. The gene for the helper protein was also included on the transfer vector along with the H1 gene. As two proteins were thus required for efficient expression of H1, Medicago's technology used for the production of H1–VLPs is described as a 'coexpression' technology.

Large-scale production of the *Agrobacterium* culture required two phases: a small-scale propagation phase and a larger expansion phase. In the first phase, *Agrobacterium* was propagated from a working cell bank through shake flasks until transfer into a 125-l fermentor to achieve the bacterial mass required for the infiltration process. The fermentation was accomplished in a batch mode, and substrate utilization, optical density, oxygen, pH, and agitation speed were monitored throughout the fermentation cycle. Once a fermentation batch of *Agrobacterium* was obtained, the *Agrobacterium* was diluted in a suitable diluent in a stirred stainless-steel process vessel. This solution was fed to the infiltration unit during the infiltration operation. A constant solution level was maintained in the unit during the infiltration period.

Once plants and *Agrobacterium* were confirmed to meet specifications for process use, vacuum infiltration was used to introduce the *Agrobacterium* into the interstitial space in the leaves. This operation required a contained environment due to the number of organisms used and required plants that were contained in a substrate/container system that was amenable to movement into the area and then infiltration; hence, field-grown plants are not a good choice for transient expression that is infiltration driven. Plants were placed by robotics into trays and transported via conveyors into a containment suite for infiltration. All materials and solutions, including process intermediate, used in production in these process areas were treated to kill or remove any *Agrobacterium* before release from the containment area. Vacuum infiltration was performed batch wise with a specified number of plants infiltrated per cycle. Infiltration cycle parameters were monitored and controlled to provide a robust process. Figure 6 contains a picture of the infiltration unit used during operations.

Production: Processing

Once infiltrated, plants were placed in an environmentally controlled chamber under strict conditions for temperature, light intensity, and light exposure cycle for a specified period of time to allow protein expression and VLP accumulation in the leaves of the plant. After incubation, leaves of the plants were harvested manually and placed on a conveyor. The biomass was transported via conveyor to a dicer and the leaves were cut into small squares. Diced leaves were transported via conveyor to a stainless steel, mechanically agitated digestion

vessel that contained an enzymatic solution. The enzymatic solution allowed digestion of the structural components of the diced leaves and released the VLP from the plant biomass. Reaction conditions, such as agitation, pH, time, and temperature, were controlled during the release of VLP.

Once digested, VLP were recovered and residual solids and some host cell impurities were removed by clarification operations in the process. Clarification operations consist of a number of unit operations, such as centrifugation and filtration that are designed to reduce particulates and *Agrobacterium* in the process stream. After completion of digestion, the in-process solution was passed through stainless steel strainers and then transferred into a single-use 1000-l mixing vessel that fed a disk stack centrifuge. After centrifugation, the solution was filtered through a glass fiber filter and a 0.2-μm filter. The last filtration operation assured that all *Agrobacterium* were removed from the solution.

The clarified material was concentrated using a tangential flow filtration (TFF) membrane system. After concentration, the material was diafiltered to allow removal of process impurities, such as host cell proteins and small molecules. This process step was important for purification of the VLP and also for preparing the process intermediate for further purification by chromatography. Retentate from the TFF system was loaded to an ion exchange column and process impurities, such as DNA, endotoxin, and host cell proteins, were separated from the VLP. VLP were bound to the column and eluted with a step gradient to high salt content. The eluate from the ion exchange column was loaded to a second ion exchange column as a polish step. VLP were passed through the column under the loading conditions, and residual DNA and some host cell proteins were bound to the column. The material that flowed through the second ion exchange column was diafiltered on a TFF skid in order to suspend the VLP in an excipient matrix suitable for injection. The VLP solution was filtered through a 0.22-μm filter that was part of a sterile manifold containing single-use bioprocess containers. The VLP solution, drug substance, was loaded to the sterile bags, sealed with a heat sealer, and stored at 2–8 °C until use for testing purposes.

Vaccine release specifications for the drug substance were set based on previous results from analysis of clinical material produced at pilot scale. A number of release and characterization assays were performed on the drug substance. Determination of protein concentration, HA identity, residual DNA, nicotine, anabasine, RuBisCo, pH, appearance, and sterility were some of the assays performed to assure product quality. Additional characterization assays, such as mass spectrometry, dynamic light scattering, nanotracking analysis, and cryoelectron microscopy, were performed on drug substance to assess purity and structure.

Conclusions

The project was deemed successful because the facility construction was completed in approximately 1 year and the production process was transferred and scaled up 30-fold. After a series of development and engineering runs, the process was demonstrated to be ready to support manufacturing operations. At the conclusion of a 30-day manufacturing campaign, greater than 10 000 000 doses of vaccine had been produced. The vaccine met the quality attributes that had been prespecified for the vaccine and the vaccine was shown to be immunogenic in mice.

Glossary

Avirulence (Avr) factor A pathogen/pest effector recognized either directly or indirectly by the corresponding functional plant resistance (R) protein.

Effector A secreted protein or other molecule used by plant-associated organisms to modulate plant metabolism, suppress, activate, and reprogram plant defenses and thereby enable successful colonization of plant tissues.

Host-induced gene silencing (HIGS) This technique is used for silencing genes in plant-associated organisms. In HIGS, silencing is triggered directly within the plant and targets genes in plant pathogens or plant pests. Silencing induces the production of short double-stranded RNA (dsRNAs) in the host plant cells following one of the two delivery methods: (1) microprojectile particle bombardment of RNAi constructs into plant leaves or (2) stable plant transformation with RNAi constructs. It is used primarily to silence genes in obligate biotrophic species, which are not transformable via stable transformation methods.

Leucine-rich repeat (LRR) A structural motif found in many resistance (R) proteins that mediate effector-triggered immunity and also in some pattern-recognition receptors (PRRs). This type of motif contains leucines or other hydrophobic amino acids at regular intervals over a stretch of 23 or 24 amino acids. The LRR is reiterated numerous times in most plant PRR and R proteins and can occur extracellularly or intracellularly. The LRR forms a parallel β sheet structure within the protein. Within this structure, the hydrophobic leucines are in the protein interior whereas the other residues are surface exposed and form a surface capable of interacting with other proteins. Different interacting surfaces can be generated via single amino acid changes, and this permits the evolution of specific interactions. LRR motifs mediate protein–protein and receptor–ligand interactions in many organisms. The LRR motifs in plant R proteins probably participate in effector perception and PAMP perception.

Pathogen- or microbial-associated molecular patterns (PAMPs/MAMPs) Molecules associated with groups of pathogens that are recognized by host cells, via PRRs and activate the innate immune system resulting in PAMP triggered immunity (PTI). The PAMP/MAMP molecules recognized are typically small molecular motifs that are conserved within a class of microbes such as bacterial flagellin or fungal chitin.

Pathogenicity factor This is a qualitative term used to describe a gene, protein, or metabolite from a pathogenic species that is absolutely required for disease formation on at least one plant host species. In the absence of this pathogenicity factor the pathogen is unable to cause plant disease on a susceptible host plant species, but is still able to grow and develop normally on a range of *in vitro* conditions.

Programmed cell death (PCD) Death of a cell mediated by an intracellular program. PCD is carried out in a regulated process. Apoptosis and autophagy are both forms of PCD, whereas necrosis is not.

***R* gene stacking** The deliberate accumulation in an elite or semielite plant line of more than one *R* gene that effectively controls a single pathogen or pest species. *R* gene stacking is achieved though plant breeding over several generations, in a single generation via plant transformation or via a combination of the two methods.

'Stacked *R* – anti-*S* gene' T-DNA cassette The tightly linked pairing of a disease resistance gene and another type of gene that prevents /minimizes disease susceptibility. Both have been placed under the control of different promoters between the right and the left border of the transfer DNA construct used for plant transformation with *Agrobacterium tumefaciens*. Once within the transgenic plant, the desirable gene pair cannot be separated by genetic recombination.

Virulence factor This is a quantitative term used to describe the degree to which a gene, protein, or metabolite from a pathogenic species contributes to disease formation on at least one plant host species. In the absence of this virulence factor, the pathogen species is only able to cause reduced plant disease on a susceptible host plant species. Without the virulence factor, the pathogen is still able to grow and develop normally on a range of *in vitro* conditions.

Introduction

To fulfill the future demands for food, feed, and fiber of the ever-growing human population, novel crop protection strategies are required to minimize potential losses to agricultural crops from the myriads of pathogenic microbes and invertebrate pests that cause diseases and damage. These plant-infecting organisms include phytopathogenic bacteria, fungi, oomycetes (water molds), viruses, insects, and nematodes. The resulting biotic stresses cause major losses to crop yield and product quality, and when severe disease epidemics occur this can result in the complete loss of the harvest (Agrios, 2005). Globally, an estimated 20–40% reduction in agricultural production occurs each year due to pathogens and pests (Strange and Scott, 2005; Oerke, 2006). In addition, over the past few decades a steady increase in the virulence of plant-infecting organisms has been observed, making the task of pathogen and pest control even more difficult. This increase in pathogen virulence is, at least partially, caused by globalization and the increased genetic exchange between previously geographically separated pathogen and pest populations. This genetic exchange accelerates the emergence of new pathogen genotypes. In particular, increases in worldwide trade and international travel are considered to be the major routes

 doi:10.1016/B978-0-444-52512-3.00248-5

underlying the macroevolutionary genesis of plant pathogens and pests (Fisher *et al.*, 2012).

To protect crops, farmers, crop advisers/consultants and crop protection companies can deploy a range of options. These include cultural practices, for example, deep plowing of infested or infected crop residues and the rotation of different crop species, the use of conventionally bred resistant germplasm, and the application of pesticides. Pesticides can be applied as seed dressing, soil drenches, soil fumigants, or directly to the growing crop within guided spraying regimes. In many situations, an integrated pest and disease management system is deployed that combines several crop protection approaches in a single growing season.

Over the past 25 years, plant biotechnology has emerged as an additional control option, which can be used either alone or in conjunction with the other crop protection options. The use of plant biotechnology has for a long time been considered the best route to enhance the performance of an already high-yielding elite plant genotype. The plant biotechnology approach is used to try to eliminate the elite cultivars susceptibility to a major pest or pathogen prevalent in a particularly important geographical region or country (Stuiver and Custers, 2001; Hammond-Kosack and Jones, 2000; Hammond-Kosack and Parker, 2003).

In this article, innovative genetic engineering approaches devised to improve crop protection by providing a novel form of resistance that may also be more durable will be described alongside the original underpinning basic science discoveries. In a few instances genetically engineered plant solutions are now fully adopted by farmers and are in commercial use. These successfully adopted examples have already been described in detail in two earlier articles of this Encyclopedia. Enhanced insect resistance in many crop plant species based on the overexpression of different *Bacillus thuringiensis* (*Bt*) endotoxins (BT toxins) is the second most widely used trait (after herbicide resistance) present in commercial genetically modified crops. The global adoption of BT crops has been recently reviewed by Tabashnik *et al.* (2013) and Chen *et al.* (2011).

The focus of this article is the novel plant biotechnology solutions already available which could, in the future, be used to enhance the repertoire of crop protection strategies available against one or more pathogen or pest species. The most promising solutions have been successfully tested in replicated field trials done in one or more geographical locations. However, for the majority of the novel plant biotechnology solutions described in this article the only data available have so far been generated exclusively in glasshouses or in other controlled environments. The most recent comprehensive reviews on this topic are provided by Dangl *et al.* (2013), Atkinson *et al.* (2012), Collinge *et al.* (2010), Dodds and Rathjen (2010) and Gust *et al.* (2010).

Breakthrough Scientific Discoveries and New Scientific Resources Available for Exploitation

Fundamental research done over the past 25 years has led to an increasingly clear conceptual understanding of the two-tiered plant defense system. Within this new knowledge framework exciting opportunities have emerged to improve crop disease resistance via plant biotechnology. At the same time, the underlying pathogen and pest processes recognized as absolutely required for different types of infection, colonization, and disease development have emerged. These fundamental new insights have also been targeted to provide novel plant-specified inhibitory mechanisms via plant biotechnology.

Plant Detection of Nonself

For a plant to respond to attack by a potential pathogen or pest, each plant cell must recognize the threat of nonself. This is now known to be based on the recognition of conserved pathogen- or microbial-associated molecular patterns (termed PAMPs or MAMPs) or damage-associated molecular patterns (DAMPs), such as plant cell wall fragments released via wounding or pathogen attack, by PAMP recognition receptors (PRRs) (reviewed by Zipfel and Robatzek, 2010). The best known true PAMP is the major constituent of the fungal cell wall, chitin. Chitin is released from the fungal cell wall by the action of plant chitinases. Chitin-binding PRR lysine motif (LysM) receptors have been described in *Arabidopsis*, rice, and wheat (reviewed by Lee *et al.*, 2014). Chitin-binding PRR proteins present at the plant cell surface in the plasma membrane recognize the presence of a fungal invader and thereby rapidly activate several plant defenses that result in PAMP-triggered immunity (PTI) (**Figure 1**). Other PAMPs detected by plants include bacterial flagellin and bacterial elongation factor EF-Tu. Defense responses activated following PAMP recognition include the production of reactive oxygen species (ROS), such as superoxide anions ($\bullet O_2^-$) and hydrogen peroxide (H_2O_2), which damage pathogen membranes and act as additional plant signaling molecules. The rapid thickening of plant cell walls at the penetration sites via callose deposition also occurs. Upstream of these defense responses, there is a rapid and coordinated induction of specific ion fluxes as well as the activation of plant protein kinases, regulatory proteins such as the redox sensitive signaling protein NPR (see Section Systemic Plant Defense Responses) and transcription factors. These responses increase the signaling complexity and further enhance the local plant defense response. Often a range of toxic metabolites accumulate at the infection site, thereby further inhibiting pathogen growth or pest feeding. This highly localized response immediately restricts nutrient acquisition by the pathogen or pest and this minimizes their further progress.

PTI places selective pressures on all potential pathogenic species to produce proteins or other compounds known as effector molecules, which interfere with and suppress these defense mechanisms or their activation. This is known as effector-triggered susceptibility (ETS) (**Figure 1**). Successful plant pathogens, nematodes, and insects secrete a plethora of effectors to circumvent or suppress plant defenses (de Wit *et al.*, 2009; Dodds and Rathjen, 2010). The induction of ETS is a common prerequisite to a successful host–pathogen or host–pest interaction that requires the presence of living plant cells through all or just the early phase of the infection (see Section Different Pathogen and Pest Lifestyles). Pathogen and pest effectors can be divided into those that function extracellularly, termed apoplastic effectors, and those that function

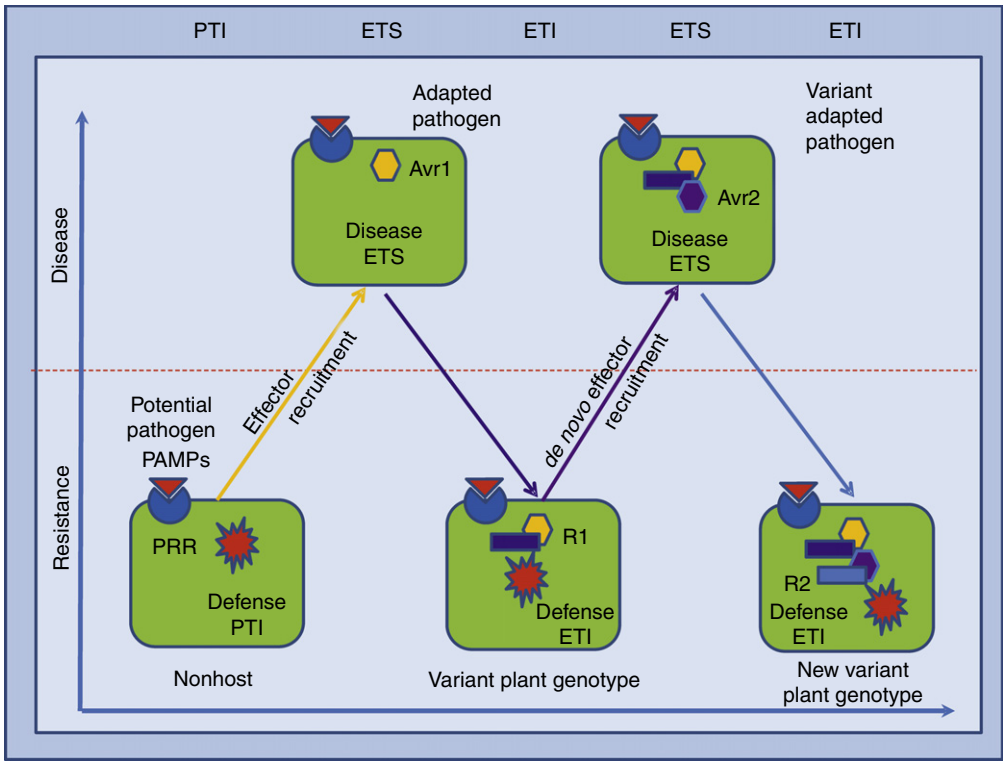

Figure 1 The zig-zag-zig model. The evolutionary arms race between pathogen and host is represented by the sequential activation of layers of plant defense and by the acquisition of novel effectors, resulting in either disease resistance or disease susceptibility (disease). Phase 1: PAMP recognition and PAMP-triggered immunity (PTI). Phase 2: The adapted pathogen evolves or acquires an effector (Avr1) that circumvents PAMP recognition, resulting in effector-triggered susceptibility (ETS). Phase 3: A variant plant with the ability to express the resistance protein (R1) that is capable of directly or indirectly detecting the presence of Avr1, resulting in effector-triggered immunity (ETI). Phase 4: A variant adapted pathogen evolves or acquires an additional effector, Avr2, resulting in ETS. Phase 5: A new variant plant with the resistance protein (R2) capable of directly or indirectly detecting Avr2, resulting in ETI.

from within the host cell, termed cytoplasmic effectors. To increase protein stability, secreted apoplastically accumulating effectors tend to be cysteine rich whereas those translocated and subsequently functioning in the plant cytoplasm are rarely cysteine rich.

Successful plant colonization is achieved through the production and delivery of specialist pathogen- and pest-effector molecules. This places selective pressure on the plant population to recognize these effectors and the consequence is the activation of defense responses. These variant plants found in natural populations, germplasm collections, or created during plant breeding have alleles of resistance (*R*) genes that recognize either a subset of the effector molecules (direct recognition) or the effects of these effectors on other 'guarded' host proteins (indirect recognition). This form of defense is known as *R* gene-mediated defense, or effector-triggered immunity (ETI) (**Figure 1**). The receptors that lead to the direct or indirect recognition of pathogen effectors and then trigger ETI can either be intracellular, as is the case for nucleotide binding site–leucine-rich repeat (NBS-LRR) receptors, or extracellular such as LysM and LRR receptors that possess short transmembrane domains with or without a cytoplasmically located kinase domain (reviewed by Jones and Dangl, 2006). The local defense responses triggered during ETI include rapid synthesis and release of various ROS, activation of specific ion fluxes, protein kinase cascades and transcription factors, papillae formation, single host cell death termed the hypersensitive response (HR), accumulation of defense-related/pathogenicity-related (PR) proteins, and various antimicrobial proteins. The local defense reactions triggered by ETI are usually, but not always, stronger than those triggered by PTI (Jones and Dangl, 2006). For historical reasons, many effector-encoding genes were first called Avirulence (Avr) genes because their presence in the pathogen is recognized by a corresponding plant *R* gene.

Resistance protein-mediated activation of ETI places a selective pressure on the pathogen to evolve and recruit new effectors to provide the same function as the now defeated effectors (**Figure 1**). Once a suitable effector is successfully selected or evolved, the adapted pathogen is able to cause disease once again on the host plant species via ETS. This ETI-ETS-ETI cycle can be reiterated numerous times and the eventual outcome is now known to be influenced by the activities of plant breeders, local and global climatic conditions, as well as by the presence of other pathogenic species.

In summary, in the interaction between a successful pathogen and its plant host, on the pathogen side there is a constant acquisition or loss of effectors, whereas on the host side there is a constant recruitment or loss of proteins that detect these effectors. This is described by the 'zig-zag-zig' model (Jones and Dangl, 2006, **Figure 1**). Others have since

invoked an evolutionary framework to the original 'zig-zag-zig' model, and describe this series of molecular changes to both the pathogen and the host as an evolutionary arms race (Chisholm *et al.*, 2006; Dangl *et al.*, 2013). The molecular interactions that mediate ETI are predominantly represented by small proteinaceous effectors and exclude the broader-acting secreted secondary metabolites, toxins, and plant substrate-degrading enzymes. Although examples that conform to the 'zig-zag-zig' model are now well documented for many plant-infecting fungi, bacteria, viruses, and nematodes, currently this fundamental information is far more fragmentary for insect pests (Hogenhout *et al.*, 2009).

For plant-pathogenic fungi and bacterial species that deploy host-selective toxins for successful infection and tissue colonization, a different interaction model is proposed. This is most frequently referred to as the 'inverse gene-for-gene' model (Oliver and Solomon, 2010). Pathogen virulence must be dominant because of the need to produce a functional toxin or enzyme to cause disease; whereas, plant resistance is predominantly inherited as a recessive trait and resistance is achieved via the loss or alteration of the toxin target.

Systemic Plant Defense Responses

In some plant–pathogen interactions, the formation of localized necrosis at the point of initial infection during ETI leads to the activation of a subset of defense responses in distal plant tissues. The type of systemic response induced is determined by the identity of the initial attacking organism. Systemic responses induced to fungi, bacteria, and viruses are distinct from those of insects. Nematodes induce a blend of the two response types. For all plant species, the adaptive advantage of orchestrating systemic responses is enormous because this ensures that the distant plant tissues can deal more effectively with subsequent attacks. Fungi, bacteria, and viruses activate a phenomenon known as systemic acquired resistance (SAR) (reviewed by Spoel and Dong, 2012). SAR requires at least four plant-derived signaling molecules and four plant-derived signaling proteins that operate either locally or distally or are transported through the vasculature. Studies done on tobacco and *Arabidopsis* have identified the key molecules to be (1) salicylic acid (SA), (2) methylsalicylic acid and the vasculature mobile signals, (3) azelaic acid, and (4) glycerol-3-phosphate. The key proteins required locally to initiate SAR are the (1) low-affinity SA receptor protein NPR3 and (2) the redox-sensitive signaling protein NPR1, which shuttles between the cytoplasm and the nucleus. The NPR1 protein binds to TGA (TGACG motif-binding) transcription factors, thereby enhancing their binding to SA-responsive plant promoters. Post the arrival of the signaling molecules in the distal tissues, (3) the high-affinity SA receptor NPR4 functions in conjunction with the NPR1 protein, and (4) the apoplastic lipid-transfer protein DIR1 to promote defense-gene induction without causing host cell death. SAR leads rapidly to the transcriptional activation of a wide repertoire of defense responses and considerable pathogen resistance. Another type of systemic plant response is called induced systemic resistance (ISR) or 'priming', which can be activated by either non-pathogenic root-colonizing bacteria or the application of synthetic chemistry, including β-aminobutyric acid (BABA) (reviewed by Conrath *et al.*, 2006).

Herbivorous insects mechanically wound the plant tissue while feeding and induce the rapid accumulation of proteinase inhibitors (PIs) and defense proteins throughout the plant. This systemic response is often referred to as the wound response. An 18-amino acid polypeptide called systemin is the mobile systemic signal. In tomato, once systemin reaches the target tissue, a lipid-based signaling cascade is activated, which is reliant on jasmonic acid (JA) production and ethylene biosynthesis. This in turn induces the expression of PI and other defense genes (Reymond *et al.*, 2000; Schilmiller and Howe, 2005).

Of the three systemic responses described, SAR is the phenomenon that has most frequently been exploited by plant biotechnology (see section Use of Defense-Signaling Components).

Different Pathogen and Pest Lifestyles

Among the pathogenic species that cause disease on plants, huge variation exists in their modes of infection and the methods subsequently deployed to sustain the acquisition of sufficient nutrients from extracellular and intracellular sources that are needed to complete each pathogen's *in planta* lifecycle. Plant-pathogenic fungal, oomycete, and bacterial species are generally subdivided according to their *in planta* nutritional strategy. Biotrophs acquire sustenance for extended periods only from live plant cells, whereas necrotrophs rapidly kill the host plant cells and live on the released nutrients. However, not all plant pathogens clearly fit into these two distinct categories. Many plant pathogenic species are now recognized to have an initial transient phase reminiscent of a biotroph, followed by a later necrotrophic phase. These pathogens are classified as either hemibiotrophs or latent necrotrophs and the duration of the biotrophic phase can be very short (1–2 days) or extend over several weeks (Agrios, 2005; Oliver and Solomon, 2010). Some fungal and oomycete species, in addition to using filamentous hyphae to colonize plant tissue, also form specialist feeding structures inside plant cells called haustoria to facilitate the acquisition of nutrients. When devising novel crop protection strategies through plant biotechnology, the lifestyle of the pathogenic species and its intracellular versus extracellular location in the plant tissue needs to be considered carefully. Likewise, the potential to cause undesirable outcomes needs to be evaluated. For example, would a strategy devised to control a biotrophic species lead to enhanced susceptibility of the transgenic crop to necrotrophic species?

A multitude of insect species feed, reproduce and shelter on plants. Two main insect categories are recognized: those that chew and those that suck sap. Chewing insects cause the greater plant tissue damage. For example, species of locusts and Colorado potato beetle as well as the larvae of many insect species can defoliate an entire crop within a couple of days. Other chewing insects feed only on roots or seeds. Crop protection by the ingestion of BT toxin takes advantage of the chewing habit of these insect species (Vaeck *et al.*, 1987). The sap-sucking insects, such as adult aphids, trips, or leafhoppers,

cause minimal direct tissue destruction. Instead, feeding occurs via a specialized mouth part, the stylet. The phloem sieve elements in the plant's vascular tissue are located, penetrated, and the sap removed. When present in high numbers, sap-sucking insects cause chronic shortages of photosynthates and lead to a severe reduction in plant growth. Many of these insect species also transmit plant viruses.

When insects feed, specific plant volatiles are released from the feeding sites and these can act as both attractants and deterrents to further colonization by the same or other insect species. Considerable insight into the complexity of insect–plant volatile communication events is beginning to be gained by analyzing the changes to air composition during insect-feeding events and exploring insect-neural stimulations in response to specific plant volatiles. The largest group of plant volatiles discovered to date is the terpenes, a diverse class of secondary metabolites, which includes monoterpenes (C_{10}) and sesquiterpenes (C_{15}). One of the best characterized plant-produced sesquiterpene volatiles is (*E*)-*β*-farnesene (EBF). For many aphid species, EBF is the principal constituent of the aphid alarm pheromone (Beale *et al.*, 2006). The constitutive production of EBF by plants could hold promise in the control of specific aphid pests (see Section Enhancing Resistance Against Insect Pests).

Soil-dwelling plant parasitic nematodes – tiny roundworms approximately 1 mm long – feed on plant roots and more than 20 genera of nematodes are known to cause plant disease. Nematode infections are nearly always confined to the plant root system. However, the plant's entire metabolism can be drastically altered, the roots become swollen and distorted and, as a consequence, the crop's yield and quality can be dramatically reduced. Sedentary endoparasitic nematodes, which are obligate biotrophs, are by far the most crop-damaging ones globally. These include root-knot nematodes (genus *Meloidogyne*) and cyst nematodes (genera *Heterodera* and *Globodera*) species. These species possess a hollow feeding stylet that penetrates plant cell walls and eventually permits a feeding sedentary female nematode to spend 30–40 days gaining sustenance from highly modified xylem parenchyma cells. Ectoparasitic nematodes feed exclusively at the root surface (Agrios, 2005).

In recent years, a number of key scientific breakthroughs made in plant-nematode research are potentially exploitable through plant biotechnology (reviewed by Atkinson *et al.*, 2012). These include the identification of plant-specific chemical signals released by healthy roots that induce the hatching of the juvenile nematode from the dormant egg. For the potato and soybean cyst nematodes the hatching factors identified are solanoeclepin A and glycinoeclepin A, respectively. The nematodes then invade the roots in the zone of elongation, migrate inwards to the vasculature, and then activate at a selected site in the xylem parenchyma the expression of specific plant genes. Once feeding commences, the nematode become sedentary (nonmotile). The feeding of each sedentary female nematode over the next 30–40 days induces the formation of either highly modified giant cells or syncytial structures. The plant promoters recovered from these induced genes are particularly valuable for targeting the expression of different types of anti-nematode proteins directly to the feeding sites (see Section Engineering Nematode Resistance). Furthermore, some of the candidate effectors secreted by nematodes through the stylet, which are hypothesized either to facilitate feeding or to suppress plant defenses, have been identified through proteomics analysis of nematode gland secretions (Bellafiore *et al.*, 2008).

The Availability of Fully Sequenced Plant, Pathogen, and Pest Genomes

The sequencing of entire plant genomes and the systematic profiling of changes to the plant transcriptome in the presence or absence of specific pests and pathogens is already underway across the 'tree of plant life.' This sudden influx of new comparative data on an unparalleled scale, initially significantly enhanced our understanding of the plant-immune system in the diploid model plant *Arabidopsis thaliana* and the diploid crop species, rice. Since the mid-2000s, there has been an ongoing reduction in sequencing costs, improvements in sequencing technology, and a refinement of the bioinformatics tools available to assemble genomes and transcriptomes, to predict the gene repertoire of each species and assign other key genomic features, for example, transposons, repeat-rich regions, gene clusters, and the sequences potentially coding for regulatory microRNAs and gene promoters. As a consequence of these large community endeavors, extensive genome and transcriptome information has rapidly become available for most agriculturally important crop plant species, which have much larger and often polyploid genomes. Major new resources are now available in the public domain for all the major cereal species, i.e., maize, barley, wheat, sorghum, foxtail millet, and many key vegetable, fruit, and commodity crop species, including coffee, tomato, potato, cassava, and banana. With this abundance of new information on plant genomes, the potential *R* gene repertoire for many plant species has now been defined and is available for immediate exploitation (see Section Relevant Websites).

Sequencing the entire genomes of important pathogens and pests has been ongoing since the mid-1990s. By defining the complete repertoire of predicted genes for a given plant-pathogenic or pest species, and by comparing the content and layout of each genome, this is beginning to provide researchers with a wealth of new information to better understand pathogen and pest biology. In this context, intercomparing the genomes and gene content of free-living and plant-associated species is very informative. This genomic information also provides clues to the range of intercellular and extracellular molecules (proteins and metabolites) produced by pathogens and pests that may be detected by plant cells. The genomic era for plant-infecting pathogens began with the sequencing of plant viruses and viroids, then plant-pathogenic bacteria, and recently has embraced a full range of plant-pathogenic fungi, oomycetes, plant parasitic nematodes, and insect pests.

By comparing the whole genomes of many different strains or isolates of the same pathogenic species, the candidate effector gene sets that may be responsible for key biological differences can be pinpointed and then experimentally assessed for function. In many studies, the transcribed portion (transcriptome) of the pathogen or pest genome specifically expressed *in planta* has also been characterized in detail, in an

attempt to identify the putative effector sequences and induced metabolic pathways. Today, fully sequenced genomes for hundreds of agriculturally important pathogenic species are now available (Raeffaele and Kamoun, 2012; The International Aphid Genomics Consortium, 2010). Major breakthroughs include sequencing the complex genomes of the oomycete *Phytophthora infestans*, which causes late blight of potatoes and tomatoes, the barley powdery mildew *Blumeria graminis* f. sp. *hordei* and the pea aphid *Acyrthosiphon pisum* (see Section Relevant Websites). Within the next 5 years, the number of species with full genome sequence information is predicted to rise to several thousands. This wealth of new information on pathogens and pests is already being harnessed by plant biotechnologists and plant breeders through effector guide *R* gene selection (see Section Defining the Pathogen-Effector Repertoire to Guide *R* Gene Choice).

Harnessing New Knowledge on Pattern-Recognition Receptor Proteins and R Proteins

To recap briefly, pattern-recognition receptors (PRRs) detect microbes by recognizing PAMPs. Different plant families carry distinct repertoires of PRRs that perceive distinct PAMPs, whereas most resistance proteins directly or indirectly recognize pathogen and pest effectors and this results in the local activation of plant defenses.

Utilizing Cloned Pattern-Recognition Receptor Genes

One biotechnology approach that has been successfully applied to control a range of pathogenic species is to transfer PRRs between plant species. The *Arabidopsis* PRR protein called elongation factor Tu (EF-Tu) receptor (EFR) perceives the acetylated *N*-terminus of the bacterial EF-Tu through binding to the LRR ectodomain. In the solanaceae, the bacterial EF-Tu is not perceived. Transfering the EFR from *Arabidopsis* into tobacco (*Nicotiana benthamiana)* and tomato (*Solanum lycopersicum*) has conferred responsiveness of these recipient plants to bacterial elongation factor Tu and elevated resistance to several phytopathogenic bacteria species representing different genera. The species controlled included *Agrobacterium tumefaciens*, *Pseudomonas syringae*, *Ralstonia solanacearum*, and *Xanthomonas perforans* (Lacombe *et al.*, 2010). These results suggest that extending the PAMP recognition repertoire of crop plants can lead to broad pathogen resistance. The identification of additional functional PRRs and their transfer to a recipient plant species that lacks the orthologous receptor protein could provide a general way of broadening resistance in agriculturally important plant species. In theory, this may even reduce the range of pathogenic species able to cause disease on the recipient plant species and thereby reduce the overall crop protection requirements needed for the crop. With climate change predicted to change gradually the range of important pathogenic species present in a particular geographical region or country, the transfer of species- or family-specific PRRs could potentially become an important route to tackle newly emerging pathogen problems.

The PRRs FLS2 and EFR that recognize bacterial flagellin and EF-Tu, respectively, both require the LRR receptor kinase BAK1 to mediate protein heterodimerization resulting in PTI (Chinchilla *et al.*, 2007, 2009). In rice, overexpression of the interacting protein OsBAK1 was shown to significantly enhance resistance to the rice blast fungus *Magnaporthe oryzae* (Hu *et al.*, 2005; Li *et al.*, 2009). The transgenic OsBAK1 rice plants also had improved grain yield and plant architecture. This indicates that enhancing disease resistance does not necessarily limit the plant's intrinsic potential to grow, develop, and produce an abundant harvest.

Utilizing Cloned Plant Disease Resistance (*R*) Genes

Traditionally plant breeders have introgressed, via time-consuming and lengthy breeding programs, new *R* genes from wild relatives of crop species into elite commercial cultivars to control diseases (**Figure 2(a)**). Within the elite breeding programs, the desired *R* gene introduced via introgression must also be recombined away from any genetically linked bad alleles of other genes coming from the wild relative that may reduce crop performance ('linkage drag'). Often plant breeders try to deploy multiple *R* genes simultaneously in a single elite line, in a breeding strategy known as *R* gene stacking. Through this approach the new cultivar or advanced breeding line possesses multiple *R* genes, each controlling one or at best a few pathogens. However, these *R* genes are located in different regions of the genome and particularly important *R* gene combinations could be lost in subsequent plant generations via genetic recombination. Therefore, marker-assisted selection (MAS) using primer combinations within each *R* gene is needed to ensure that in each breeding generation the required *R* gene stack is maintained (reviewed by Pavan *et al.*, 2010).

The availability of cloned *R* genes now opens the possibility of their direct transfer into elite plant breeding lines by genetic transformation. Plant transformation enables the transfer of several different *R* genes effective against a single pathogen species in a 'cassette' of linked genes that cannot be separated by recombination (**Figure 2(b)**). This multi-*R* gene cassette in theory should slow down pathogen evolution to overcome resistance, because the various *R* genes could only be overcome if, in a single pathogen isolate, several effector genes were simultaneously mutated. However, a major disadvantage of the stacking of single *R* genes is that once the pathogen mutates one of the recognized cognate effectors, plant resistance is no longer triggered by that *R* gene and the overall defense response activated may be weakened. The assembled multiple *R* gene stack would immediately become more vulnerable to further changes in the effector repertoire of the pathogen population.

The introduction of *R* genes by plant transformation also means that the interplant species fertility barriers can be crossed, thereby increasing the repertoire of plant species from which useful novel resistance sources can be obtained, for example, from a distally related wild species. Most *R* gene sequences when transferred from the original plant species to a closely related species confer resistance. However, some *R* genes also function in entirely different plant families. For example, barley Mla can function and confer powdery mildew

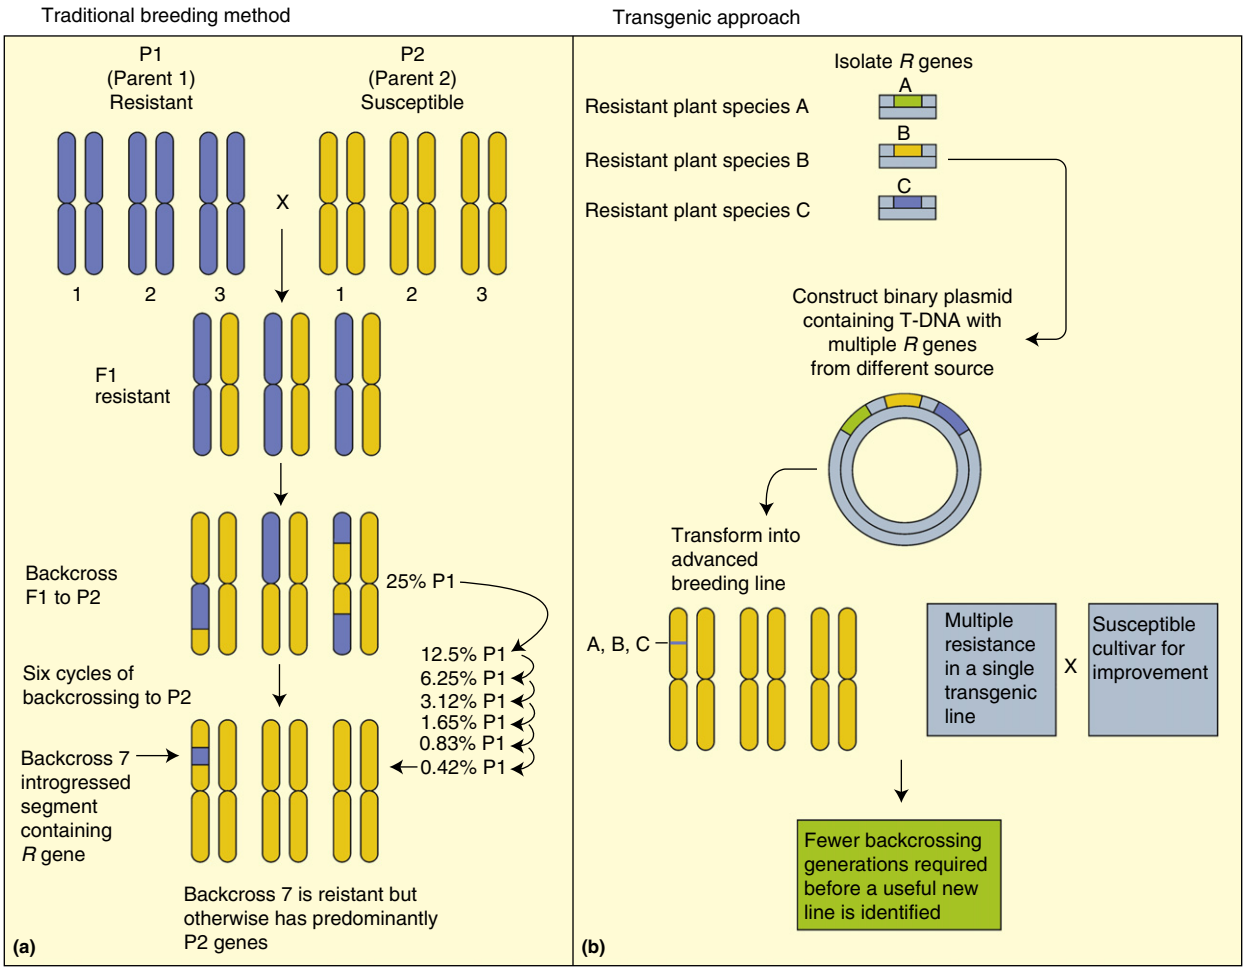

Figure 2 The traditional breeding approach is compared with plant transformation technology to introgress desirable genes into commercial crop plants. (a) In a traditional breeding program, as much as 0.4% of the genome complement from each donor parent can reside in the seventh backcross generation along with the *R* gene of interest (originally from parent 1). (b) By the transgene transformation approach, multiple *R* genes from several initial sources are first assembled into a single Ti plasmid. After T-DNA integration into the plant genome, these *R* genes cosegregate in all subsequent breeding steps, greatly simplifying the subsequent backcrossing program for introducing multiple new traits into a cultivar. When the transgenic transformation approach is used, the entire sequence of the introduced DNA is known, whereas in the traditional breeding program, neither the total extent of the DNA introgressed nor its sequence identity is known. Reproduced from Hammond-Kosack, K.E., Jones, J.D.G., 2000. Responses to plant pathogens. In: Buchanan, B.B., Gruissem, W., Jones, R.L. (Eds.), Biochemistry and Molecular Biology of Plants. Rockville, MD: American Society of Plant Physiology, pp. 1102–1156, with permission from American Society of Plant Biologists.

resistance in *Arabidopsis*, and *Arabidopsis* RPS4 and RRS1 can function in solanaceae (Narusaka *et al.*, 2013). The later success is particularly interesting because the transfer of *R* gene-based defense to a distantly related species required the identification of the correct pair of *R* genes and then their simultaneous transfer. *R* genes that confer resistance to all or almost all isolates/races of a particular pathogen species are particularly attractive candidates for interspecies transfer because it is plausible that they will confer the same broad-spectrum resistance as occurs in their 'native' genomes.

One of the most impressive examples of the use of *R* genes from another species, introduced through plant biotechnology to control a devastating plant pathogen, involves the potato crop and the oomycete pathogen *P. infestans*, which causes late blight disease. *Phytophthora infestans* caused the complete loss of the Irish potato crop between 1845 and 1852 and was responsible for the Irish potato famine that led to the death of ~1 million people and the emigration of ~1.5 million people from Ireland. Currently, most cultivated tetraploid potato varieties are either fully or partially susceptible to *P. infestans* and, as a consequence, a very comprehensive chemical spraying program throughout the growing season is required to control this pathogen, often in excess of 10 foliar sprays per season. In contrast, most accessions of the wild diploid potato species, *Solanum bulbocastanum*, are highly resistant to all known races of *P. infestans*. Using a map-based cloning experimental strategy from a cluster of four highly related *R* genes of the NBS-LRR sequence type, the resistance gene *RB*/*Rpi-blb1* was isolated. Transgenic cultivated potato plants (*Solanum tuberosum*) expressing the *RB* gene show a high level of resistance to nearly all *P. infestans* isolates, including a recent European 'super race' that can overcome all 11 known *R* genes in cultivated tetraploid potato (Song *et al.*, 2003).

Two other *R* genes conferring broad-spectrum resistance to *P. infestans* have been isolated, again from wild potato species, namely *Rpi-blb2* from *S. bulbocastanum* and *Rpi-vnt1.1* from *Solanum venturii* (Dixelius *et al.*, 2012). Transgenic cultivated potato lines expressing both the *Rpi-blb1* and *Rpi-blb2* genes have been evaluated over several years in field trials in the United Kingdom and mainland Europe. Enhanced control of late blight disease has now been achieved via this route (Jones *et al.*, 2014). The use of plant biotechnology to improve plant disease resistance is especially important in plant species like the potato, where conventional plant breeding is inherently difficult and where no useful resistance exists within the germplasm pool available for agriculturally important species.

Many race-specific R proteins are temperature sensitive. For example, at temperatures above 30 °C, *N* gene-mediated resistance to tobacco mosaic virus (TMV) fails and virus particles spread systemically throughout the plant. With climate changes now being experienced in many global regions, inconsistent pathogen control may arise by using temperature-sensitive *R* genes. A lack of correct R protein folding and/or incorrect cellular localization is the most plausible reason for this phenomenon. Plant biotechnologists need to determine carefully the effective temperature range of each *R* gene before their deployment to avoid this undesirable outcome.

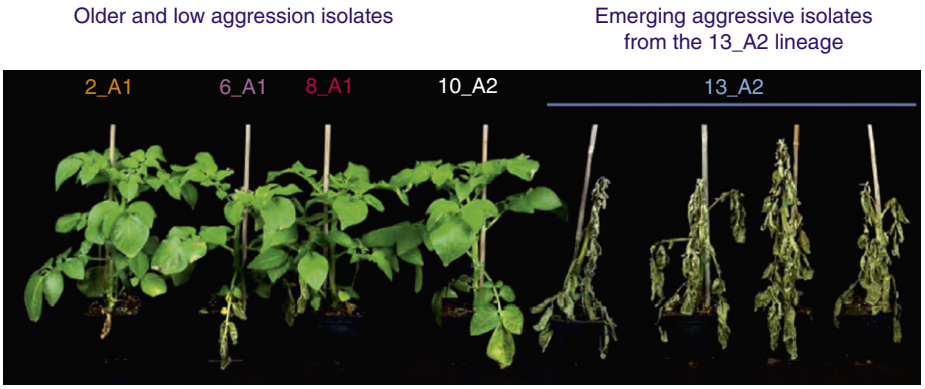
Defining the Pathogen-Effector Repertoire to Guide *R* Gene Choice

Whether by breeding or by plant transformation, isolating new *R* genes from wild relatives by map-based cloning is laborious. Before commencing such an approach, it is desirable to prioritize those *R* genes that are most likely to be durable. An analysis of pathogen-effector complements can help. If a *R* gene recognizes an effector that is conserved in all known races of a pathogen, called a 'core effector,' it is more likely to be durable than if the *R* gene recognizes an effector that is absent from many races of the pathogen. In addition, some effectors have been shown to be essential for the full disease-causing ability of the pathogen. By targeting these essential pathogen effectors, resistance is again more likely to be more durable. Emerging knowledge of differences in the effector complement between pathogen races can be extremely helpful when choosing which *R* genes to prioritize for use in plant biotechnology. Within the past 15 years the number of pathogen and pest species for which full genomic sequence information is now available and readily accessible has steadily risen (see Section The Availability of Fully Sequenced Plant, Pathogen and Pest Genomes).

In the potato/*P. infestans* interaction, effector-guided *R* gene deployment is already in use (reviewed by Oliva *et al.*, 2011). This new approach, which in the future can be applied to control many other plant pathogens and pests, is described in detail in **Figure 3**.

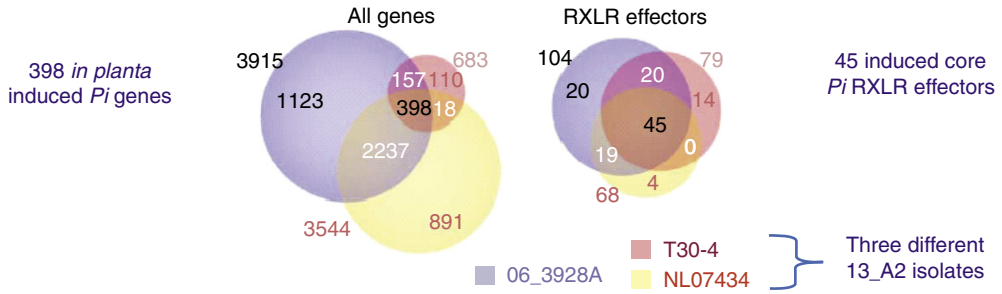
In a geographical region where severe disease epidemics have emerged and become commonplace, rapid and inexpensive DNA-sequencing technologies can provide, in just a few days, genome-scale information on natural field isolates of the pathogenic species causing the problem. By this route, it is possible to explore each genome and compare these with the reference genome for the species held 'on line' in various public databases (see Section Relevant Websites). Any effector changes occurring both within and beyond the core effector complement can be rapidly recognized. Effector-guided *R* gene deployment is now being deployed to identify durable resistance genes against the new Ug99-derived races of the wheat stem rust fungus *Puccinia graminis* f. sp. *tritici*, which threatens wheat harvests in Africa and Asia. Recently, the *Sr35* gene that confers near immunity to Ug99 and related races has been isolated from *Triticum monococcum*. The cloning of *Sr35*, which encodes an NBS-LRR protein, opens the door to the use of biotechnological approaches to control this devastating disease (Saintenac *et al.*, 2013).

Cassava (*Manihot esculenta*) is one of the staple crops of East Africa. The causal agent of cassava bacterial blight, *Xanthomonas axonopodis* pv. *manihotis* (*Xam*), can devastate this crop. Full genome sequencing of ~65 *Xam* strains collected over a 70-year timeframe, from 12 countries and three continents has revealed a core effector set, which can now be used to define the repertoire of *R* genes activated by each effector in wild *Manihot* species and potentially other related plants in the family Euphorbiaceae (Dangl *et al.*, 2013). Once several cognate *R*-gene sequences have been identified a transgenic route will be used to rapidly introduce into cassava the most appropriate *R* gene combinations, i.e., an *R* gene stacking approach, in an attempt to achieve durable control as shown in **Figure 2(b)**.



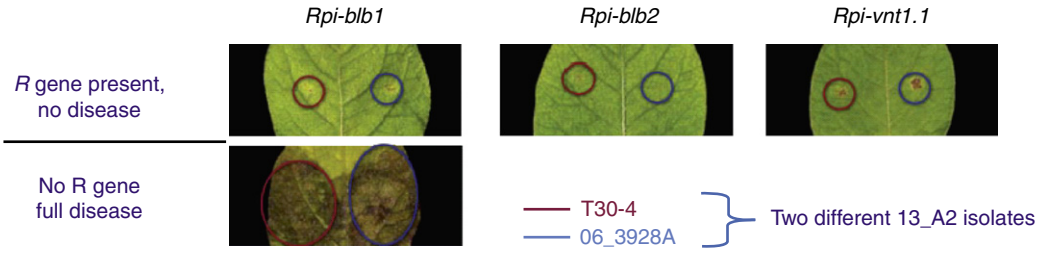
Isolation and Deployment of Broad-Spectrum *R* Genes

For many decades, some plant *R* genes already present in crop species have conferred resistance to many or all races/strains of a single pathogenic species. For example, members of the recessively inherited *mlo* resistance gene family, already functionally characterized in barley, *Arabidopsis*, and tomato, confer resistance to all races of the adapted powdery mildew species (Consonni *et al.*, 2006; Bai *et al.*, 2008). Other *R* genes that confer broad-spectrum resistance include the barley *Rpg1* gene against stem rust infections (Brueggeman *et al.*, 2002; Horvath *et al.*, 2003; Mirlohi *et al.*, 2008), and the *Arabidopsis RRS1-R* against several strains of the bacterial wilt pathogen, *R. solanacearum* (Deslandes and Rivas, 2012). Searching for and isolating other *R* genes from crop species and their wild relatives that provide broad effector recognition capabilities for a particularly problematic pathogen species is a very valuable research activity.



Another set of *R* genes confer resistance to multiple unrelated pathogenic species. For example, the tomato *Mi-1.2* gene, which encodes a NBS-LRR type of R protein, confers resistance to the root-knot nematode *Meloidogyne incognita*, the potato aphid *Macrosiphum euphorbiae*, and the whitefly *Bemisia tabaci* (Nombela *et al.*, 2003). Some other *R* genes confer resistance to different but taxonomically more closely related pathogenic species. For example, the *Lr34* gene in hexaploid wheat, which encodes an ATP-transporter protein, confers resistance to leaf rust (*Puccinia recondita*) and stripe rust (*Puccinia striiformis* f. sp. *tritici*) (Krattinger *et al.*, 2009). The two *Arabidopsis RPW8* genes mediate broad-spectrum powdery mildew resistance (Wang *et al.*, 2009). The deployment of

Effector guided *R* gene deployment



(a) Explore the disease causing ability of historic and current *Phytophthora infestans (Pi)* isolates.

(b) Whole genome sequencing and *in planta* transcriptomics used to identify the 45 'core' RXLR *Pi* effectors present in 3 isolates from lineage 13_A2 that are also expressed early during leaf infection.

(c) The conserved core effectors *Avrblb1*, *Avrblb2*, and *Avrvnt1* are present in all 13_A2 isolates. These are recognized when the corresponding *R* gene is expressed.

(d) Stack *R* genes that recognize different conserved *Pi* effectors to confer durable resistance by plant biotechnology or marker assisted selection.

Figure 3 Effector-guided *R* gene deployment based on the identification of 'core effectors' that lack sequence polymorphism. The core effector-guided *R* gene strategy is currently being used in potato (*S. tuberosum*) to mitigate the impact of the 13_A2 lineage of the late blight pathogen, *Phytophthora infestans.* This pathogen undergoes major population shifts in agricultural systems via the successive emergence and migration of asexual lineages. (a) The aggressive lineage, termed 13_A2, in the European *P. infestans* population, is rapidly displacing the other older lineages. (b) The method used to identify the core effector repertoire in the new aggressive lineage of *P. infestans.* (c) The 13_A2 isolates carry intact and *in planta* induced *Avrblb1, Avrblb2,* and *Avrvnt1* effector genes that trigger resistance in potato lines carrying the corresponding disease resistance genes *Rpi-blb1*, *Rpi-blb2,* and *Rpi-vnt1.1.* This core effector-guided approach can also be used to exclude from the elite potato germplasm improvement scheme any *R* genes already defeated because the cognate core effectors contain sequence polymorphisms that evade plant recognition. (d) *R* gene stacking is achieved by the two methods described in **Figures 2(b)** and **4**. Reproduced from Figures 4A, 7A, and 8B in Cooke, D.E.L., Cano, L.M., Raffaele, S., *et al.*, 2012. Genome analyses of an aggressive and invasive lineage of the Irish potato famine pathogen. PLoS Pathogens 8 (10), e1002940.

broad-spectrum *R* genes is particularly worthwhile in geographical regions where many destructive pathogen and pest species (i.e., disease–pest complexes) are prevalent.

Further isolation and characterization of *R* genes of this type will ensure that the largest tool kit is available for plant biotechnologists to exploit and engineer broader spectrum disease resistance in crops in the future. In particular, analysis of the ever increasing abundance of genome sequence information and transcriptome sequence information available for crop species should reveal the *R*-gene sequences most similar to those genes known to confer broad-spectrum resistance. These can then be preferentially tested for function via plant transformation.

Widening Resistance Protein Recognition Specificity

Within the zig-zag-zig model (Figure 1), two main types of R proteins are recognized: Those that directly bind the cognate Avr effector and those that indirectly confer resistance by guarding another protein, which can itself bind several different effector proteins (Jones and Dangl, 2006; Dodds and Rathjen, 2010; Dangl *et al.*, 2013). This complexity permits a range of plant biotechnology options to be used to widen the specificity of recognition.

Exploiting the Effector-Recognition Domain

Only a small subset of R proteins directly bind the cognate Avr effector. A study of Avr effector recognition in the *Melampsora lini*–flax interaction generated a series of chimeric L-locus (*R* gene) immune-receptors that contained swaps between and within protein domains. Interactions between these modified immune-receptors and the fungal effectors were evaluated *in vitro* and via transient expression *in planta*. Some of these chimeric immune-receptors were found to have an enhanced ability to detect different races of *M. lini* and induce a defensive response. This demonstrates the usefulness of engineering plant receptor proteins to widen the repertoire of Avr effectors (secreted by the feeding fungal haustoria) that are recognized by the plant cells. This new approach to R protein engineering could potentially be used to generate cultivars with disease resistance to other species of rust pathogens in a range of agricultural crops, once the cognate *Avr* and *R* genes are isolated and characterized (Ravensdale *et al.*, 2011, 2012).

Mutagenizing the Leucine-Rich Repeat Recognition Domain

Many plant R proteins possess a LRR domain. The variable regions in the LRR are implicated in microbial effector recognition and in determining resistance specificity (reviewed by Jones and Dangl, 2006; Dodds and Rathjen, 2010). In potato, the Rx protein confers resistance to potato virus X (PVX). The Rx LRR domain recognizes variants of the viral coat protein (CP). By using a novel PCR-based method that permits random mutagenesis specifically in the DNA sequences coding for the LRR domain, artificial *Rx* alleles were generated that conferred resistance to several additional PVX strains and to several strains of the unrelated poplar mosaic virus (Farnham and Baulcombe, 2006). Artificially targeting the 'evolution' of *R* gene sequences in the laboratory appears to have great potential for engineering plant resistance and for broadening natural *R* gene specificity against diverse pathogens. For many R proteins the subdomains in the LRR region conferring microbial effector recognition and determining resistance specificity are already well known and well characterized. The exploitation of this approach depends on the development of rapid and cost-effective ways to identify the novel variant alleles of greatest commercial interest.

Blocking Pathogen-Effector Uptake into Plant Cells

This plant biotechnology approach is only just beginning to emerge as a consequence of the wealth of new knowledge on how some effectors from oomycete and fungal species are taken up into plant cells. Interfering with effector function is a powerful way to control microbial function, albeit potentially only in a pathogen-specific manner. The identification in the *N*-terminus of the highly conserved RxLR (arginine, any amino acid, leucine, arginine) and dEER (aspartate (less conserved), glutamate, glutamate, arginine) motifs in the secreted effectors of many oomycetes, including *Phytophthora*, *Hyaloperonospora*, and *Albugo* species, enabled the identification of a novel mode of effector uptake into host cells that is similar to that deployed by the malaria parasite *Plasmodium* to gain entry into human cells (reviewed by Tyler, 2009; Raeffaele and Kamoun, 2012). The development of a disease control strategy based on blocking effector uptake has been made possible because the mechanisms used in different *Phytophthora* species and different core effectors has been established. For example, in certain species, by applying a blocking agent to prevent phosphotidylinositol-3-phosphate (PI-3-P) binding, effector uptake into the plant cell was inhibited (Kale *et al.*, 2010). Subsequently, cacao plants (*Theobroma cacao* Linn.) were transformed to secrete transiently excess PI-3-P, which somehow inhibited effector uptake. The modified cacao leaves when inoculated with *Phytophthora palmivora* showed a reduction in lesion size, demonstrating the successful application of this concept to lessen the impact of this devastating fungal disease in tropical regions (Tyler *et al.*, 2011). Unfortunately, in other oomycete species binding PIPs has been shown not to be required for effector uptake. Similarly, the well-studied effector protein AvrM secreted by the flax rust fungus *M. lini* has been shown to bind PIPs, but this binding is not required for effector internalization (Ve *et al.*, 2013). Whether this novel plant biotechology approach has wide applicability or instead proves to be a highly species specific control option is currently unclear.

Following on from these impressive oomycete discoveries, researchers are searching for a highly degenerative RxLR-like motif in a wide range of fungi, including plant, insect, and mammalian pathogens. Such a discovery could enable the application of the aforementioned approach, tackling effector uptake, to a wide range of fungal diseases. In this context, the identification of an enrichment of the Y/F/WxC in the *N*-terminus of the mature protein may be important. The first amino acid of this motif is aromatic tyrosine, phenylalanine, or tryptophan, and the last is always cysteine. The high

abundance of the motifs in the predicted secretome repertoires of several unrelated haustoria-forming obligate biotrophic fungal species (i.e., many that cause leaf and stem rusts, or powdery mildew) (Godfrey *et al.*, 2010) is intriguing and may be exploitable in the future. Similarly, in rice blast (*M. oryzae*) research, an important plant-derived structure formed post hyphal invasion, called the biotrophic interface complex (BIC), has been discovered. The BIC transports a subset of *M. oryzae* effectors into the rice cells in advance of fungal infection (reviewed by Valent and Khang, 2010). The BIC provides a new target location inside infected plant cells for possible exploitation by plant biotechnology. In each interaction, blocking uptake of the core effectors is likely to be the most successful route.

Removal of Plant-Susceptibility (S) Targets

Two new genome-editing methods have been developed for use in plants during the past 10 years. These are (1) transcription activator-like effector nucleases (TALENs) (Boch, 2011; Schornack *et al.*, 2013) and (2) clustered regulatory interspaced short palindromic repeat (CRISPR) technologies (Jinek *et al.*, 2013; Gaj *et al.*, 2013). In the future, either technology could be used to remove pathogen-susceptibility targets from crop plant species. In breeding for resistance, elimination of disease susceptibility genes (*S* genes) has been proposed as a viable alternative to exploitation of *R* genes (Gust *et al.*, 2010). Moreover, deploying a single-gene editing approach should ensure that all other genes in the plant genome and especially those in the vicinity of the *S* gene are maintained in elite crop plant germplasm. However, this needs to be cautiously done for two reasons: Some plant proteins are now known to be targeted by multiple effectors that are sequence unrelated. These diverse effectors come from different pathogen species. Therefore, creating resistance to one pathogenic species might increase susceptibility to another species. Second, some susceptibility targets perform other plant functions as well and are required for normal plant growth and development (discussed further by Gawehns *et al.*, 2013).

Arabidopsis RIN4 is a negative regulator of ETI and is targeted by numerous Pseudomonad bacteria effectors. As a consequence, the plasma membrane-tethered RIN4 protein is guarded by several R proteins, including RPM1 and RPS2 (reviewed by van der Hoorn and Kamoun, 2008). This is a classic example of indirect recognition of an effector by an R protein (Jones and Dangl, 2006). The use of CRISPR or TALEN technology to remove this effector-targeted host protein should enhance disease resistance. However, due to genetic redundancy of effector function, this approach might weaken ETI-mediated defense in situations where the pathogen rapidly evolves to recruit and use other effectors for virulence and thereby make better use of an alternative negative regulator of ETI that is less well guarded by R proteins.

For plant-pathogenic bacteria in the genus *Xanthomonas*, TAL (transcription activator-like) effectors called Transcription activator-like effectors (TALEs) contribute to pathogen virulence and the disease formation process by binding directly to host DNA and transcriptionally activating specific *S* genes that are beneficial to the pathogen's growth and dissemination (Boch and Bonus, 2010). To date, these are the only type of bacterial effectors known to function in this way. This discovery led to the description of a new type of DNA-binding protein and opened up the possibility of targeting specific plant genes.

TALEs produced by the bacteria *Xanthomonas oryzae* pv. *oryzae* (*Xoo*) contribute to virulence by transcriptionally activating specific rice *S* genes (Li *et al.*, 2012). Molecular engineering has been used to create a wide array of TAL effector nuclease (TALENs) fusion-proteins (Boch, 2011; Schornack *et al.*, 2013). TALENs contain the DNA recognition repeats of native or customized *Xoo* TAL effectors and the DNA cleavage domains of FokI nuclease. To engineer rice to be resistant to *Xanthomonas*-incited bacterial blight, the promoter of the rice susceptibility gene *Os11N3* (also called *OsSWEET14*) was targeted for TALEN-based disruption. This gene encodes a member of the SWEET sucrose-efflux transporter family. Two *Xoo* TAL effectors, AvrXa7 or PthXo3, activate this *S* gene and divert plant sugars to the bacteria, whereas a third effector PthXo1 targets a different *S* gene. The *Os11N3* promoter contains binding sites for the AvrXa7 or PthXo3 effectors near the TATA box. The TALENs were designed to mutate DNA required for the susceptibility function, but not the development function of Os11N3. Therefore, post transformation the rice lines were first screened by PCR for mutations in both TAL-effector binding sites, but leaving the TATA box intact. This modified *Os11N3* gene was no longer inducible when the rice plants were infected by *Xoo* strains that deliver either the AvrXa7 or PthXo3 effectors into plant cells. The stable TALEN-modified plants showed strong (though recessive) resistance to infection by the AvrXa7- or PthXo3-dependent *Xoo* strains but not the PthXo1-dependent pathogenic *Xoo* strain (Li *et al.*, 2012). So far, natural polymorphisms in the *Os11N3* gene that would confer disease resistance have not been identified in rice germplasm. By using the TALENs to edit precisely a rice gene required for *Xoo* susceptibility, desirable alleles conferring resistance can now be used in rice breeding programs.

In many successful plant breeding programs to control fungi, bacteria, and viruses, recessively inherited disease-resistance genes are well known and well used. In these situations, the lack of a susceptibility protein target or the production of a nonfunctional protein variant is hypothesized to be the underlying cause of these recessively inherited traits. One of the best studied recessive *r* gene is *mlo,* which has functional orthologs in barley, tomato, and *Arabidopsis* (Consonni *et al.*, 2006; Bai *et al.*, 2008). The wild-type *MLO* allele codes for a seven transmembrane-spanning protein that is required for susceptibility to powdery mildew. A subset of the secreted powdery mildew effectors, presumably successfully target MLO to aid fungal infection of the plant's epidermal cell layer. MLO protein families are present in many other crop species, each colonized by different adapted powdery mildew species. Interestingly, the virulence function of the *P. syringae* effector HopZ2 was found to target *Arabidopsis* MLO2, and plants harboring T-DNA inserted into *mlo2* alleles were found to exhibit resistance to this unrelated pathogen (Lewis *et al.*, 2012). Therefore, inactivation of the plant-susceptibility factor MLO in a range of crop species, by using precise genome editing, should confer resistance to different devastating powdery mildew species and potentially other unrelated pathogens.

In *Arabidopsis*, genetic dissection of susceptibility to powdery and downy mildews has identified multiple *S* genes whose impairment results in disease resistance. The *Arabidopsis S* genes *PMR4* and *DMR1* encode a callose synthase and homoserine kinase, respectively, and both genes have functional orthologs in tomato. Single-gene silencing in transgenic tomato plants, using RNAi constructs resulted in resistance to the powdery mildew fungus *Oidium neolycopersici*. However, resistance to *O. neolycopersici* by *DMR1* silencing was associated with severely reduced plant growth whereas *PMR4* silencing was not (Huibers *et al.*, 2013). Therefore, *PMR4* is currently the more suitable candidate gene for immediate deployment via plant biotechnology. This highlights the fact that S proteins have more than one function and are often important for plant growth and development.

Targeting Pathogenicity Factors

Removal of Essential Secreted Biomolecules

In a few fungal and bacterial species the secretion of a single biomolecule has been shown to be essential for the disease-causing ability of the species. In these scenarios, plant biotechnology approaches that either eliminate or reduce drastically the production of these essential biomolecules should enhance disease resistance. This approach has been particularly successful in controlling the necrotrophic fungus *Sclerotinia sclerotorium*, which infects hundreds of crop species. Oxalic acid (OA) secreted by *S. sclerotorium* is a key pathogenicity factor (Cessna *et al.*, 2000). The plant enzyme oxalate oxidase (OXO) can oxidize OA into carbon dioxide and hydrogen peroxide. Transgenic crop plants, including oilseed rape, hybrid poplar trees, potato, soybean, peanuts, and sunflower overexpressing OXO from a range of different cereal plant sources exhibit very high resistance to infection and disease symptom formation (Dong *et al.*, 2008; Stuiver and Custers, 2001). This approach appears to have been particularly successful because the reduced OA production prevents the rapid acidification of the plant tissue that, in turn, probably prevents an arsenal of secreted *S. sclerotorium* enzymes from rapidly macerating the plant cell wall. In addition, the hydrogen peroxide generated would act as a local signal and activate plant defenses.

Bacterial Quorum Sensing

Bacteria have adopted a community genetic regulatory mechanism, known as quorum sensing (QS), to gain maximum benefit in a competitive environment. Many pathogenic and nonpathogenic bacterial species use QS signaling systems to synchronize the expression of specific target genes and thereby coordinate the biological activities locally in the population. *N*-acylhomoserine lactones (AHLs) are well-characterized QS signals in Gram-negative bacteria, which regulate virulence and surface film (biofilm) formation. Several groups of AHL-degradation enzymes have been identified in bacteria and eukaryotes (reviewed by Dong and Zhang, 2005). Expression of these degrading enzymes in transgenic plants has been shown to quench efficiently the microbial QS signaling and thereby block infection by the bacterium (Dong *et al.*, 2001; Dong *et al.*, 2004). Although this approach shows promise, the real impact of overexpressing AHL-degradation enzymes on other plant-beneficial bacteria in the ecosystems is not yet known.

Minimizing Plant Cell Wall Degrading Enzyme Function

Many hemibiotrophic and necrotrophic fungal and bacterial species secrete a cocktail of plant cell wall degrading enzymes (PCWDEs) to facilitate plant infection and subsequent colonization. Owing to high gene copy numbers and functional redundancy, individual types of PCWDEs, for example, endo- and exopolygalacturonases, pectinases, and cellulases, have rarely been shown through reverse genetics experimentation to contribute to pathogenicity (reviewed by Tonukaria *et al.*, 2000). However, when plant polygalacturonase-inhibitor proteins (PGIPs) were overexpressed in various cereal and noncereal species, this led to enhanced resistance to several different ascomycete fungal species (reviewed by De Lorenzo *et al.*, 2001). These results indicate that reducing the effectiveness of pathogen-secreted PCWDE could be an important route to control pathogens that feed on or need to significantly remodel plant cell walls during infection.

Use of Host-Induced Gene Silencing

RNA interference (RNAi), also referred to as posttranscriptional gene silencing, has emerged in the last few decades as a powerful genetic tool in many eukaryotic species. The silencing starts with the initial processing or cleavage of a precursor dsRNA or a structured (hairpin) sRNA into short (20–25 nucleotides) small-interfering RNA (siRNA) duplexes by the highly conserved dsRNase-like enzymes called Dicers. The resulting double-stranded (ds) siRNAs are incorporated into an RNA-induced silencing complex (RISC) containing an Argonaute protein that has an RNA-binding domain and an endonucleolytic activity for cleavage of target RNAs. The activated RISC then unwinds the siRNA in an ATP-dependent reaction, to generate an antisense strand that targets complementary mRNA transcripts via base-pairing interactions. The subsequent cleavage of the targeted mRNA by siRNA-guided RISC causes a reduction in the amount of the corresponding protein (Castel and Martienssen, 2013).

The RNAi mechanism has recently been harnessed to control several globally important fungal pathogens using a novel *in planta* technique called host-induced gene silencing (HIGS) (reviewed by Lee *et al.*, 2012). During HIGS, the silencing mechanism is induced in fungal pathogens by expressing sequences in plants that are complementary to either 'essential for life' or essential pathogenicity genes in the fungus. By an unknown mechanism(s), the silencing phenomenon is transferred from the transgenic host plant cells to the fungal cells during the interaction, and this leads to a dramatic reduction in *in planta* fungal growth (Nowara *et al.*, 2010). Recently, two successful applications of this new approach have been reported. Firstly, in wheat, three *Puccinia triticina* (leaf rust) pathogenicity genes, the mitogen-activated protein kinase 1 (Pt*MAPK*), cyclophilin (Pt*CYC1*), and calcineurin B (Pt*CNB*)

were reported to suppress partially the growth of *P. triticina*, as well as the related wheat-infecting rust species *P. graminis* (stem rust) and *P. striiformis* (yellow or stripe rust) (Panwar *et al.*, 2013a,b). The second success was achieved by devising a stacked RNAi cassette that could target all three paralogous members of a cytochrome P450 lanosterol C-14α-demethylase gene family called CYP51 in the fungus *Fusarium graminearum*. In fungi, the CYP51 proteins are required for ergosterol biosynthesis and the maintenance of membrane integrity and are the target of the globally important sterol demethylation inhibitor (DMI) class of fungicides (Cools and Fraaije, 2008). The *in planta* expression of dsRNA complementary to CYP51A, CYP51B, and CYP51C rendered *Arabidopsis* and barley plants highly resistant to *Fusarium graminearum*, with mycelial growth restricted to the inoculation sites (Koch *et al.*, 2013). These later results are particularly encouraging and suggest that HIGS of CYP51 genes could be used as an alternative to chemical control options for a whole range of fungal pathogens.

Enhancing Plant Defense-Signaling and the Overexpression of Key Defense Components

All plant species mount a multilayered defense response following infection by pathogens or attack by pests. Once the infection/attack is perceived, a sophisticated array of defense-signaling cascades and networks are activated. These, in turn, induce a multifaceted defense response that includes the production of hydrolytic enzymes, antimicrobial compounds, antifeeding compounds, secondary metabolites, ROS, cell wall fortification, and often local programmed cell death (PCD). Most of the early attempts to engineer enhanced plant defense via plant biotechnology were aimed at overexpressing individual components from this complex response (reviewed by Hammond-Kosack and Jones, 2000; Stuiver and Custers, 2001).

Use of Defense-Signaling Components

One approach that has been well tested involves engineering plants to constitutively produce a key defense signal molecule to activate a broader array of defense mechanisms simultaneously, thereby controlling more than one pathogenic species.

Through the molecular genetic dissection of the *R-Avr*-gene-mediated ETI and the SAR response, plant genes such as *NPR1* have been isolated that are required for both the local and systemic-induced resistance. The NPR1 protein interacts with TGA-type transcription factors that control the expression of many defense-induced genes (see Sections Plant Detection of NonSelf and Systemic Plant Defense Responses). Constitutive overexpression of NPR1 from a strong promoter (i.e., 35 S from CaMV or a plant ubiquitin gene) leads to enhanced disease resistance in many species, including *Arabidopsis*, tobacco, wheat, rice, and apple, without apparently causing detrimental effects on other plant traits (Spoel and Dong, 2008; Chern *et al.*, 2005; Makandar *et al.*, 2006). The successful engineering of enhanced resistance via this approach suggests that in untransformed plants these NPR1 proteins are present in limiting concentration, and that elevating protein levels in the transgenic plants results in either the constitutive activation of defense mechanisms or the more efficient activation of defense mechanisms upon infection by a wider array of pathogens. These results also reinforce the view that the activated plant defense responses are not microbe–species specific. However, in the absence of pathogens, elevated expression of regulators such as NPR1 may result in a yield penalty.

In wheat, multiple copies of the *NPR1* gene exist and the family member functionally equivalent to *Arabidopsis* NPR1 has not yet been identified. Therefore, the native *Arabidopsis NPR1* gene was introduced into wheat under the control of the ubiquitously upregulated maize *Ubiquitin1* promoter. The floral tissue of the transgenic AtNPR1 wheat plants had enhanced resistance to the fungus *F. graminearum*, which causes head scab (Makandar *et al.*, 2006). When the wheat plants with AtNPR1 also coexpressed the *nahG* transgene that codes for the enzyme salicylate hydroxylase, which converts the signaling molecule salicylic acid into catechol, full disease susceptibility was restored. This result indicates that modified salicylic acid-mediated signaling can enhance floral defense against some fungal pathogens.

The overexpression of constitutively active forms of plant mitogen-activated protein kinases (MAP kinases) or of transcription factors that control the expression of defense–associated genes was found to confer resistance to several unrelated oomycete and fungal pathogens (Century *et al.*, 2008; Yamamizo *et al.*, 2006). However, several of the transgenic lines exhibited dwarfism, necrotic flecking, or premature senescence. This result reveals that only a carefully selected subset of alleles will go on to have commercial potential.

Several ROS are key signaling molecules produced very early *in planta* and locally during both PTI and ETI, including hydrogen peroxide. In potato, increasing hydrogen peroxide production through the apoplastic expression of a heterologous glucose oxidase enhanced the potato plant's resistance to the late blight pathogen, the oomycete *P. infestans*, the vascular wilt fungus *Verticillium dahliae*, and resistance of potato tubers to the soft-rotting bacterium *Erwinia caratovora* subsp. *caratovora*. (Shah *et al.*, 1995).

The Localized Activation of Programmed Cell Death

Localized PCD at the sites of initial pathogen entry into plants is a frequent response observed in ETI-mediated resistance to biotrophic and hemibiotrophic pathogens. The resulting hypersensitive response (HR) is hypothesized to restrict nutrient supply and this minimizes pathogen growth. Various toxic compounds synthesized by the surrounding living plant cells, predicted to restrict pathogen growth, have also been shown to accumulate preferentially in the dead cells. The infection-specific expression of various transgenes that can induce PCD was made possible by the identification of pathogen-inducible promoters and via the engineering of synthetic promoters using *cis* elements known to be rapidly activated on pathogen infection (Rushton *et al.*, 2002; Gurr and Rushton, 2005). Unfortunately, problems were encountered with the tightness of the regulation of the selected promoters. Often these promoters were subsequently shown to be 'leaky'

(i.e., expression of the PCD-inducing gene occurred in the absence of pathogen infection). As a consequence, engineering of PCD in transgenic crops may reduce infection by biotrophic pathogens or hemibiotrophic pathogens with a long latent infection phase, but favor infection by necrotrophic pathogens that thrive on the induced dead plant tissue. This point is further illustrated by the results obtained using barley plants engineered to overexpress the cell death regulator BAX inhibitor-1 (BI-1), which inhibits plant defense responses (Babaeizad *et al.*, 2009). Transgenic barley plants overexpressing the BI-1 protein grew normally and exhibited enhanced susceptibility to the obligate biotrophic powdery mildew pathogen *B. graminis* f. sp. *hordei*. The same barley seedlings overexpressing the BI-1 protein exhibited enhanced resistance to the hemibiotroph *F. graminearum* when compared with the T_3 progeny which had not inherited the transgene.

Constitutive Overexpression of Inducible Secondary Metabolites and Defense Proteins

Heterologous expression of the grapevine phytoalexin resveratrol was one of the first successful plant biotechnology solutions devised for enhanced crop protection. Tomato and tobacco plants were engineered to express the resveratrol biosynthesis pathway, by overexpression of the enzyme stilbene synthase. This resulted in resistance in tobacco to infection by various fungal species, including the fungal necrotroph *Botrytis cinerea* (Hain *et al.*, 1993) and resistance in tomato to the oomycete *P. infestans* (Thomzik *et al.*, 1997).

Plant chitinases and glucanases that target and degrade pathogen cell walls can normally only be induced following pathogen infection or as plant tissues age. The constitutive overexpression of these hydrolytic enzymes in plants has tended to result in only relatively modest improvements in plant resistance and often the effects are only against a narrow spectrum of pathogenic species. This approach was initially validated in several dicotyledonous crop species and more recently has been shown to enhance plant defense in wheat and rice to various fungal species (Gomez-Ariza *et al.*, 2007; Narasimhan *et al.*, 2009; Shin *et al.*, 2008).

Defensins are small antimicrobial proteins that come from different biological origins, including insects, marine organisms, and plants. In plants, defensins are either found in high abundance in specific organs, for example, seeds or their accumulation is strongly induced on pathogen infection, often when the jasmonic acid/ethylene-mediated defense-signaling pathway has been activated. Specific defensins have been shown to confer weak disease resistance when overexpressed in transgenic plants (Marcos *et al.*, 2008; Rahnamaeian *et al.*, 2009). Defensins directly damage fungal membranes, arrest hyphal tip growth, and cause hyperbranching. The reduced rate of fungal growth presumably gives the plant cells more time to activate additional defenses.

Engineering Nematode Resistance

Nematodes cause annual losses in excess of US$80 billion to world crops (Agrios, 2005). For many crop species, either naturally occurring genes conferring resistance to nematodes are unavailable or the breeding strategies for their deployment are inherently very slow. Transgenic approaches to control nematodes fall into two broad categories: (1) expression of inhibitory proteins and peptides to limit the nematode's dietary intake of protein from the plant and (2) prevention of root invasion but without a directly lethal effect on the nematode (Atkinson *et al.*, 2012).

Nematode feeding sites within the roots can be targeted by the use of plant promoters solely expressed in the induced syncytium or giant cells, where the nematode has lost motility and become sedentary (see Section Different Pathogen and Pest Lifestyles). The best established strategies for nematode control involve overexpression of cysteine proteinase inhibitors (cystatins) to interfere with the nematodes's digestion of plant-derived proteins. This approach has been successfully applied for the control of potato cyst nematodes (*Globodera* species) (Fuller *et al.*, 2008), root-knot nematodes (*Meloidogyne* species) infecting tomato (Chan *et al.*, 2010), as well as the migratory endoparasite species *Ditylendus destructor* that feeds on sweet potato roots (Gao *et al.*, 2011a,b) and *Radopholus similis* and *Helicotylenchus multicinctus* that feed on plantain (*Musa* spp.) roots (Roderick *et al.*, 2012). All plant parasitic nematode species must digest protein. Therefore, a cystatin-based defense can elevate resistance to several different nematode species in a single crop plant. The control of migratory nematode species is important because the root lesion formation encourages secondary fungal and bacterial infections (Duncan and Moens, 2006).

The successful invasion of host plant roots by parasitic nematodes requires each migrating juvenile animal to sense and respond appropriately to a wide range of chemical signals. Two distinct synthetic peptides have been engineered to interfere with cyst nematode chemoperception by binding to either the acetylcholinesterase or nicotinic acetylcholine receptors in the nematode's nervous system (Winter *et al.*, 2002). Transgenic plants engineered to secrete an acetylcholinesterase-inhibiting peptide from the roots decreased development of female beet cyst nematodes by more than 80% in *Arabidopsis* plants and reduced potato cyst nematode development by more than 90% in potato plants. The motile stage of the nematode is particularly vulnerable to sensory intervention (Lilley *et al.*, 2011).

Various proteins secreted from the esophageal glands of root-knot nematodes (*Meloidogyne* species) are now known to mediate infection and parasitism. The parasitism gene 16D10 encodes a conserved *Meloidogyne* secretory peptide that stimulates root growth and functions as a ligand for a putative plant transcription factor. An RNA-interference approach has been used to silence the 16D10 gene in *Meloidogyne*. *Arabidopsis* plants engineered to express 16D10 dsRNA (double-stranded RNA), resulted in effective resistance (63–90%) against the four major *Meloidogyne* species, *M. incognita*, *M. javanica*, *M. arenaria*, and *M. hapla* (Huang *et al.*, 2006).

Enhancing Resistance against Insect Pests

Several alternative approaches to the use of BT toxins to reduce insect pest numbers, plant damage, and the transmission of

harmful viruses have been developed over the past 10 years. These approaches fall into two broad categories: (1) manipulation of plant volatiles either to ward off pests or to attract natural predators and (2) prevention of insect feeding. Both approaches offer considerable promise and could be used in conjunction with BT toxins within a fully integrated pest management system.

Manipulation of Plant Volatiles

Plant volatiles are frequently released at the site of insect feeding. These volatiles can act as both attractants and deterrents to further colonization by the same or other insect species. Changes induced to the air composition in the vicinity of feeding insects have been investigated in combination with sophisticated electrophysiological equipment attached to the insects (Bruce *et al.*, 2005). This type of experimentation has revealed the existence of specific insect-neural stimulations that occur in response to specific plant volatiles. This approach and the fundamental new knowledge on the complexity of insect–plant communication events have already been exploited by plant biotechnologists in several innovative ways.

The largest group of plant volatiles are the terpenes, a diverse class of secondary metabolites that includes monoterpenes (C_{10}) and sesquiterpenes (C_{15}). One plant-produced sesquiterpene, (*E*)-β-farnesene (EBF), has been considered as a potential defense against aphids, because emission of EBF by plants causes aphids to drop off the plant or depart from the feeding site. For many aphid species, EBF is the principal constituent of the aphid alarm pheromone. When the *Ebf* synthase gene cloned from peppermint (*Mentha* x *piperita)* was overexpressed in *Arabidopsis* plants, this caused the emission of pure EBF (Beale *et al.*, 2006). These EBF emissions were shown to reduce the level of attack by aphids as well as increase the time spent on the *Arabidopsis* plants by the foraging parasitoid species *Diaeretiella rapae*. The constitutive production of EBF by plants could hold promise in the control of specific aphid pests. In the United Kingdom, the EBF approach is currently being field tested using hexaploid wheat engineered to overexpress the peppermint *Ebf* synthase gene in an attempt to control two cereal aphid species of major concern in Europe, namely the grain aphid, *Sitobion avenae*, and the bird-cherry oat aphid, *Rhopalosiphum padi* (Pickett *et al.*, 2014). Both of these insect pests are important vectors for disease-causing strains of the barley yellow dwarf virus (BYDV). Therefore, the successful control of aphid vectors should also control important plant viruses.

Following herbivory by the larvae of lepidopteran insects, maize releases a mixture of volatiles that is highly attractive to the females of various parasitic wasp species. The maize volatiles specifically released include EBF, (*E*)-β-bergamotene, and several other sesquiterpene hydrocarbons. The enzyme terpene synthase TPS10 was shown to be responsible for the formation of this mixture of volatiles from the substrate farnesyl diphosphate. Overexpression of the maize *tps10* gene in *Arabidopsis* plants resulted in the emission of high quantities of TPS10 sesquiterpene products identical to those released by maize. Females of the parasitoid *Cotesia marginiventris* learn to exploit these TPS10 sesquiterpenes to locate their lepidopteran hosts, if previously the females had been exposed to these volatiles in association with the host (Schnee *et al.*, 2006). Therefore, this single-gene approach could provide an indirect way to further boost the protection of the maize crop against herbivore attacks. The corresponding sesquiterpene synthase gene *OsTPS3* has now been identified in rice (Cheng *et al.*, 2007), suggesting that this indirect approach will be applicable to other crops and pest species.

The sesquiterpene (E)- β-caryophyllene is emitted by maize (*Zea mays*) leaves in response to attack by lepidopteran larvae like *Spodoptera littoralis* and released from roots after damage by larvae of the coleopteran *Diabrotica virgifera virgifera*. The maize terpene synthase 23 protein (TPS23) was shown to be responsible for the production of the volatile product (E)-β-caryophyllene from farnesyl diphosphate. (E)-β-caryophyllene has been shown to attract different types of natural enemies of both insect pests, namely, entomopathogenic nematodes below ground and parasitic wasps aboveground. The *TSP23* gene is transcriptionally active in teosinte species (a progenitor of maize) and European maize lines. However, for an unknown reason(s), in most North American maize breeding lines, *TPS23* transcription is decreased and this results in the loss of (E)- β-caryophyllene production (Köllner *et al.*, 2008). Restoring *TPS23* gene expression, by use plant biotechnology to introduce a fully transcriptionally active TPS23 gene sequence into North American lines should help to increase the levels of above- and below-ground pest predation and thereby improve the overall level of protection possible against these agriculturally harmful pests.

Reduction of Insect Feeding by Plant-Mediated RNA Silencing

A reduction of insect feeding has been possible for a few species by using plant-mediated RNA silencing. While feeding, many insects metabolize toxic chemicals produced by the plant to resist or evade herbivory. For example, the cotton bollworm (*Helicoverpa armigera*) is able to tolerate otherwise inhibitory concentrations of the cotton metabolite, gossypol, through the overexpression of a specific cytochrome P450, the CYPAE14 protein in its midgut. Engineered plants expressing hairpin RNA directed against CYP6AE14, when eaten by the insect larvae, provide sufficient levels of intact dsRNA to suppress gene expression in their midgut. As a result, the bollworm larvae are unable to metabolize gossypol and loose weight when feeding on cotton plants or an artificial diet containing gossypol (Mao *et al.*, 2007). However, the use of RNA silencing to control insect pests is still at an early stage compared with the use of BT crops.

Combining Approaches to Achieve Sustainable and Durable Crop Protection

In recent years, the DNA sequence length that can be inserted into a vector construct for plant transformation has gradually increased from approxiamtely 10 kb to more than 200 kb. This now means that several genes or gene-silencing constructs can be stacked and simultaneously introduced in a single

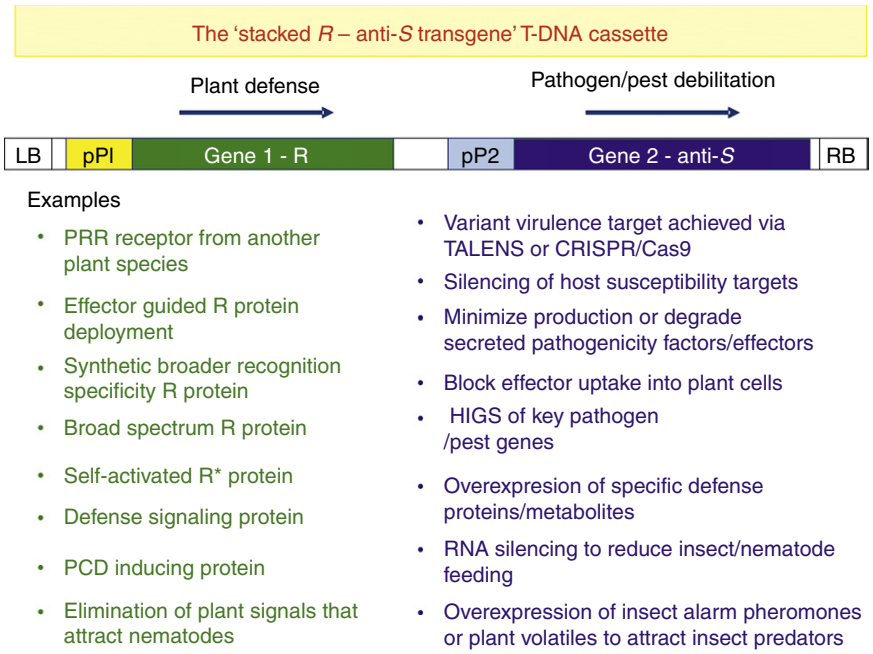


Figure 4 In the future, durable disease control could be achieved using a 'stacked *R* and anti-*S* transgene' T-DNA cassette containing two contrasting promoters and genes. The 'stacked *R* – anti-*S* transgene' T-DNA cassette approach combines the use of an effective resistance protein or defense-signaling mechanism (*R*) with a pathogen or pest debilitation mechanism to minimize plant susceptibility (anti-*S*). The *R* and anti-*S* genes are arranged in parallel and are expressed from two sequence unrelated promoters to ensure T-DNA cassette stability during the plant transformation procedure. As the repertoire of tightly regulated pathogen- or pest-inducible plant promoters gradually increases, this would permit the development of 'double-stacked *R* and anti-*S* transgene' containing two genes for each type. Alternatively, if the emphasis was on preferentially enhancing plant defense or debilitation of the pathogen, a triple-stacked *R* gene and one anti-*S* transgene, or *vice versa* could be engineered into a single T-DNA cassette. Further stacking of the unique T-DNA cassettes could also be achieved through conventional plant breeding, by creating hybrid plants or combining advanced elite pure lines. However, these multiple 'stacked *R* and anti-*S*' T-DNA cassettes (i.e., 2 genes plus 2 genes) achieved through breeding would be inherited as two distinct genetic loci. CRISPR/Cas9, clustered regularly interspaced short palindromic repeats; LB and RB, the left and right borders of the T-DNA construct; PCD, programmed cell death; pP1 and pP2, two different tightly regulated pathogen-inducible or pest-inducible promoters; R, resistance; S, susceptibility; TALENs, transcription activator-like effector nucleases; T-DNA, transferred DNA.

transformation cassette. This desirable approach has three major requirements: (1) a diverse collection of plant promoter sequences to maintain insert stability, (2) maintenance of the correct spatial and temporal pattern(s) of gene expression, and (3) a good repertoire of different gene sequence types that each confers enhanced resistance or reduced susceptibility via a distinct mechanism. In Figure 4, the types of gene stacking that are most likely to generate durable and broader spectrum crop protection are given. So far, very few plant biotechnology routes to crop protection have developed and tested this 'stacked *R* – anti-*S* gene' T-DNA cassette approach.

Conclusions and Future Prospects

The transgenic crop protection control options described have each taken immediate advantage of fundamental scientific discoveries that have advanced our overall understanding of host–pathogen interactions significantly. In each example, a target of potential vulnerability was exposed through the acquisition of new knowledge. Various intervention options were proposed and tested in the laboratory, growth room, or glasshouse and only the very best solutions went on to rigorous field testing and finally commercial release. In addition, many of the proposed single-gene transgenic disease control solutions that failed to make the grade either in early testing or later when tested under field conditions have already provided considerable useful and novel insight into the importance of other plant components and further information on the ways in which pathogens can rapidly evolve to overcome plant defenses.

In a few instances, disease resistance has been engineered using genes of animal origin. For example, one potentially powerful approach is the overexpression of antibodies that recognize microbe-specific cell surface components. Antibodies that specifically recognize a surface antigen of *Fusarium* species were fused with an antimicrobial peptide. Expression of these chimeric proteins in *Arabidopsis* or wheat conferred complete immunity to fungal infection (Li *et al.*, 2008; Safarnejad *et al.*, 2011). Although this approach provides highly efficient crop protection, the application of this technology in agricultural crops that provide human nutrition may raise ethical concerns.

Conventional plant breeding strategies targeted at delivering improved crop protection are now occurring at an accelerated pace through the increased use of high-density

molecular marker maps and wide introgression strategies. However, the pool of high-yielding elite germplasm available to plant breeders is finite. Moreover, the overall rate of evolution of the larger diploid or polyploid crop plant genomes is considerably slower than that of most pathogenic microbial species, which have haploid genomes. The other major route to crop protection is the application of agrochemicals (fungicides, insecticides, and nematicides). These products are costly to make and to apply. For example, several applications within a single growing season may be required to achieve a high level of crop protection. In addition, many active ingredients have been withdrawn over the past decade due to environmental concerns because of the potential effects on nontarget beneficial species, or because the pathogen or pest has mutated, rendering the control ineffective (reviewed by Leadbeater, 2011). The current approaches to chemical control of pathogens and pests are unsustainable in the longer term.

The current challenge is to devise novel ways to utilize the evolutionary genomic information stored in the worldwide diversity of germplasm, whether it be of plant, microbe, or pest origin. Of fundamental importance is the knowledge that most plants are resistant to most pests and pathogens, most of the time. In addition, disease and damage that does occur is usually locally restricted; either a specific part of the plant becomes diseased or damaged, for example, the leaf, root, stem, grain, or fruits, even though most organs are readily accessible. Alternatively, several organs may succumb to a pathogen or pest, but only a single specific plant tissue layer is attacked successfully, for example the epidermis, the mesophyll, or the vasculature. This means that the future solutions to pest and pathogen control already exist in the worldwide germplasm diversity. The current *in situ* and extant plant, pest and pathogen germplasm collections are of increasing importance. These key resources need to be maintained and further improved. This will ensure that these organisms and their genomes, proteomes, and metabolomes can be exploited by fundamental scientific research and for the follow-on application of plant biotechnology. Through this approach the widest possible options to achieve durable and sustainable crop protection will be available for use by current and future generations of scientists and biotechnologists to meet the growing global demands for food, feed, and fibers using less resources and less land.

Biotechnology: Regulatory Issues

T Kim, Seocho-gu, Seoul, Korea

© 2014 Elsevier Inc. All rights reserved.

Introduction

Biotechnology is an excellent, contemporary technological tool complementary to the currently established genetic improvement technologies such as selection, plant breeding, and mutational genetics. Choosing biotechnology provides an important tool for improving food productivity, quality, reducing input costs and it supports sustainable production. Development of biotech crops (or genetically modified crops) for agronomic improvements, reduced pesticides, disease tolerance, postharvest preservation, and improved nutritional quality is one of the selected applications of biotechnology in the agriculture and food sector. With the advent of molecular biology and biotechnology, it became possible not only to identify a desirable phenotypic trait but also to identify the precise genetic material responsible for that genetic trait. Recombinant deoxyribonucleic acid (rDNA) and plant transformation techniques have made it possible to alter the composition of individual plant components such as lipids, carbohydrates, and proteins beyond what is possible through traditional breeding practices. More than 16.7 million farmers around the world use agricultural biotechnology to increase yields, prevent damage from insects and pests, and to reduce farming's impact on the environment. Biotechnology improves crop insect resistance, enhances crop herbicide tolerance, and facilitates the use of more environmentally sustainable farming practices. Biotechnology is also helping to feed the world by (1) generating higher crop yields with fewer inputs, (2) lowering volumes of agricultural chemicals required by crops – limiting the run-off of these products into the environment, (3) using biotech crops that need fewer applications of pesticides and that allow farmers to reduce tilling farmland, (4) developing crops with enhanced nutrition profiles that solve vitamin and nutrient deficiencies, (5) producing foods free of allergens and toxins such as mycotoxin, and (6) improving food and crop oil content to help improve cardiovascular health (BIO, 2011; Phipps and Park, 2002; Mackey and Fuchs, 2001).

Plant biotechnology has been adopted at a higher rate than any other agricultural practice in history. Since 1996, when the first commercial biotech crops were planted, biotechnology has become the fastest technique ever adopted in agriculture. In 2011, the global area of biotech crops increased by approximately 8% from 2010 to reach 160 million hectares, up from 148 million hectares in 2010 as shown in **Figure 1**. This is a 94-fold-hectare increase since 1996. In its annual study, the International Service for the Acquisition of Agri-Biotech Applications (ISAAA) found that in 2011, 16.7 million farmers in a record 29 countries planted biotech crops, an increase of 1.3 million from the previous year. Approximately 90% of the farmers were small-scale and resource-poor farmers from developing countries. Indeed, biotech crops are helping farmers to be more productive and profitable. Biotech crop hectares continue to climb after 15 consecutive years of strong growth, as global population soars to 7 billion. The crops also contribute to a greener environment (James, 2011).

Despite the various benefits of biotech crops, the use of modern biotechnology has become a highly controversial issue in some regions where it has been applied. It has polarized modern society in terms of the potential benefits and risks of the adoption of crop biotechnologies and derived products in food and agriculture systems. The terminology for the application of biotechnology to food and agriculture has been used in various forms, such as genetic modification (GM), genetic engineering (GE), genetic manipulation, gene technology, and rDNA technology. However, the collective term 'genetically modified organisms (GMOs)' is used frequently in regulatory documents and in scientific literature to describe the deliberate introduction of DNA by human intervention into plants, animals, and microorganisms (IFST, 2008). This article covers only the safety and regulatory issues related to plant products derived by modern biotechnology, called biotech crops or genetically modified plants, not for animal products or other organisms.

Trends in the Use, Research, and Development of Foods Produced using Modern Biotechnology

Adoption of Biotech Crops

The adoption of biotech crops by the US farmers rapidly increased since the introduction of biotech crops in the US market, although the increase in adoption rate varied depending on the crops and traits (**Figure 2**). The cultivation of herbicide-tolerant (HT) soybean has increased from 7.4% of US soybean acreage in 1996 to 91% in 2007, and 94% in 2011. Plantings of HT corn, which had been slower in the early period of the last decade, has expanded from approximately 3.0% of US acreage in 1996 to 63% in 2008 and 73% in 2012. Adoption of HT cotton grew from approximately 10% of US acreage in 1997 to 80% in 2012. Plantings of insect-resistant corn and cotton containing the gene from *Bacillus thuringiensis* (*Bt*) also rapidly increased in general, although the adoption of Bt crops will likely fluctuate over time based on the expected infestation levels of major pests.

Adoption of stacked events of corn and cotton containing both HT and Bt traits has become widespread in the US (**Figures 3** and **4**). A few different techniques have been used to develop stacked events, including cotransformation, sequential transformation, or conventional crossing. Some of the already commercialized events are molecular stacks developed by cotransformation of genes included in one insert so that the event can have multiple traits. As such, transforming a host plant with an insert including multiple gene expression cassettes is a straightforward method to develop a molecular stack, which is a new biotech event developed by GE. One technical trouble in developing a molecular stack

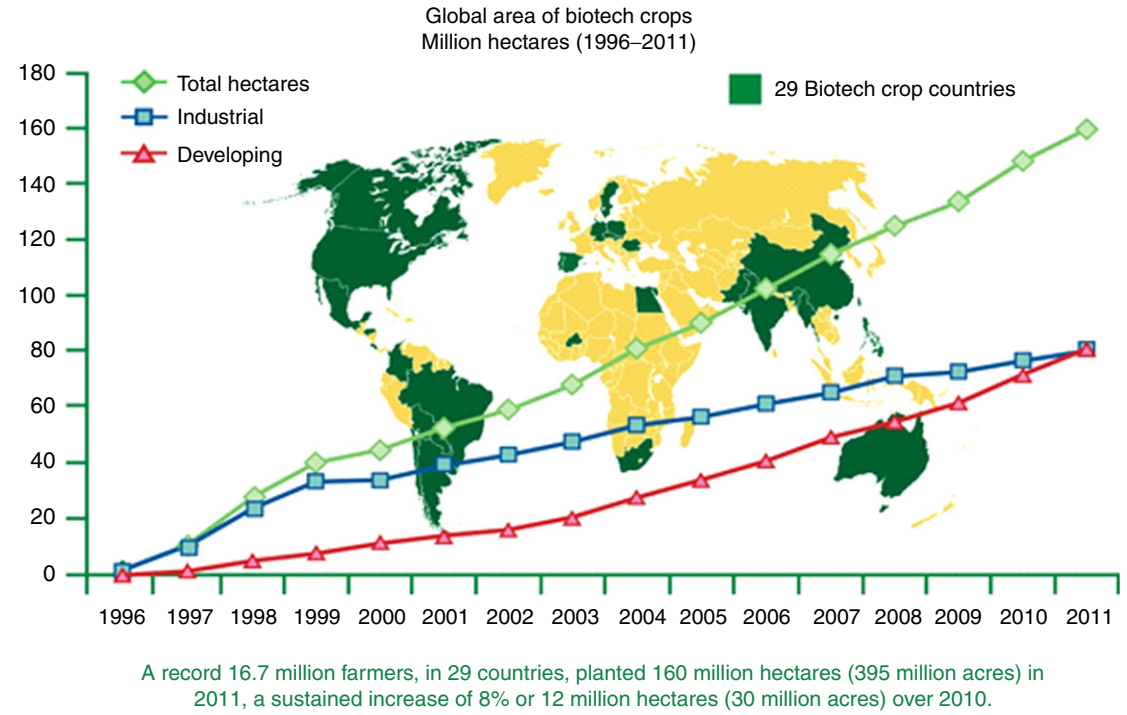

Figure 1 Global area of biotech crops. Reproduced from James, C., 2011. Global Status of Commercialized Biotech/GM Crops: 2011 ISAAA Briefs No. 43.

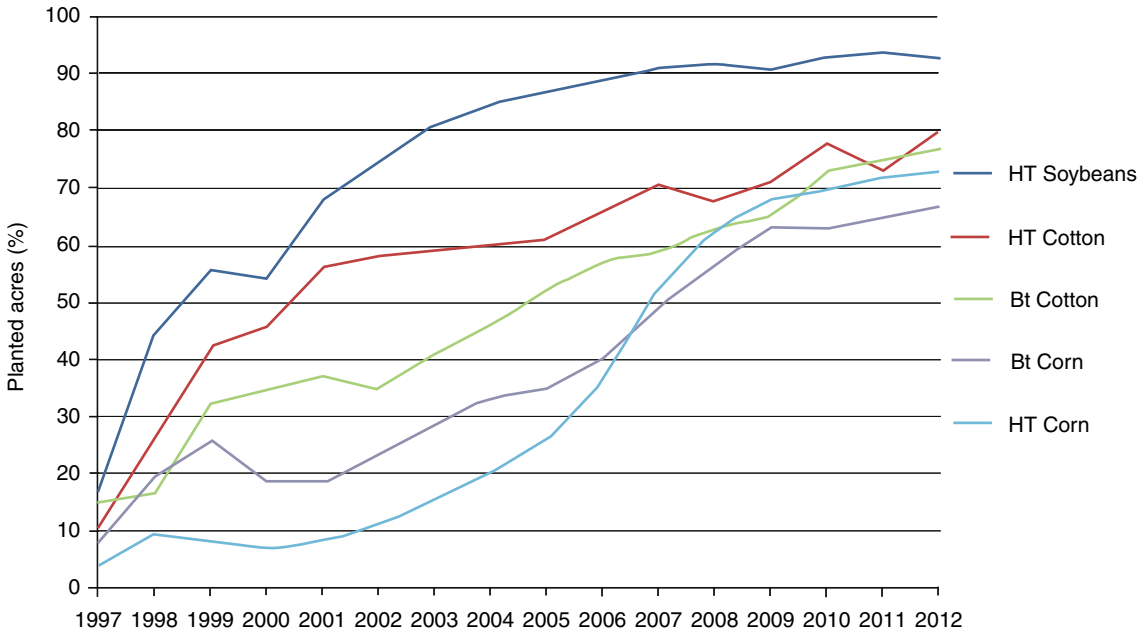

Figure 2 Adoption of biotech crops in the United States Data for each crop category includes stacked events. Reproduced from ERS, USDA, 2012.

having multiple cassettes is that the assembly of a longer insert composed of multiple gene expression cassettes is not easy.

However, genes included in respective biotech events can be combined together in diverse combinations using a conventional method, crossing between different parental lines. It is called a breeding stack. One of the advantages of breeding stacks is the flexibility in a sense that the trait combinations can be more easily tailored to specific market needs depending on prevalent pests. A key objective of pyramiding *Bt* genes in a crop is to delay emergence of Bt protein-resistant insects by stacking multiple *Bt* genes that have different modes of action, as a part of insect resistance management (IRM).

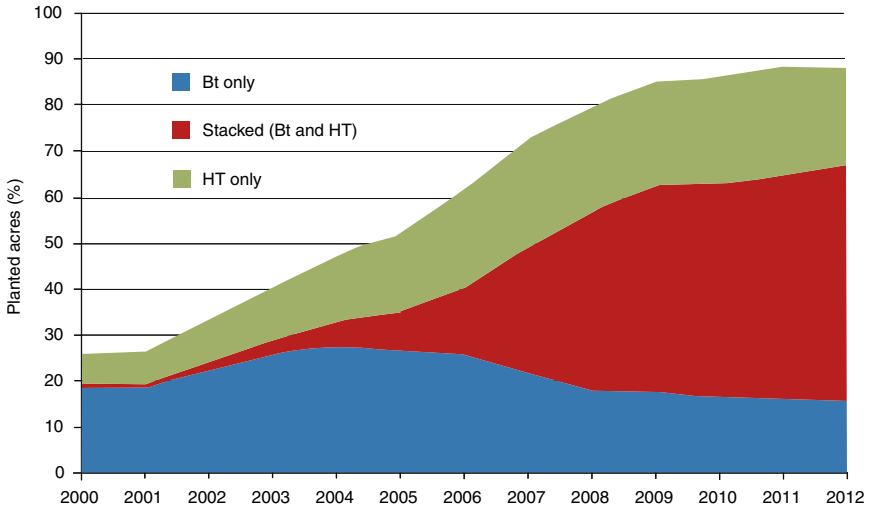

Figure 3 Adoption of biotech cotton in the United States. BT, bacillus thuringiensis and HT, herbicide-tolerant. Reproduced from ERS, USDA (2012).

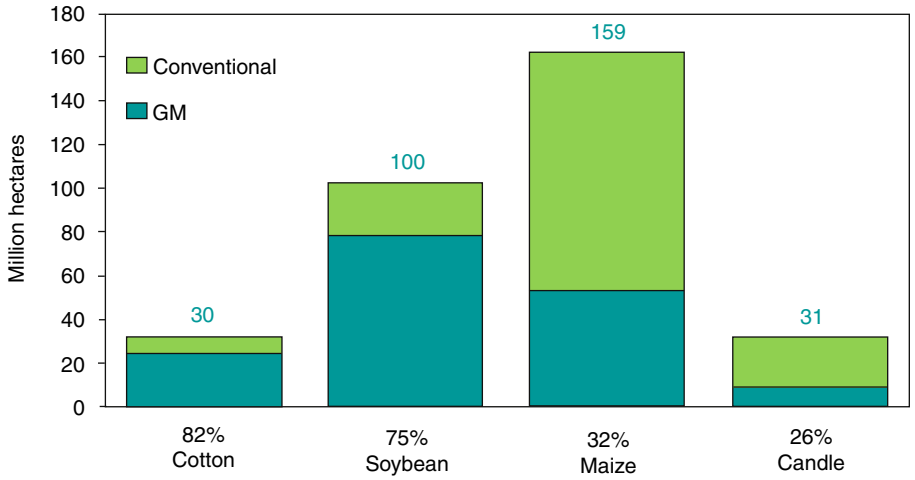

Figure 4 Global adoption rates for principal biotech crops. Reproduced from Clive James, ISAAA (2012).

Global adoption of biotech crops also has become widespread despite the controversy about efficacy and safety in some countries in the region. According to the ISAAA, global planting acreage of biotech crops has increased so that biotech crops covered 160 million hectares and planted by 15.4 million farmers in 29 countries in 2011 (Figure 1).

Commercial Traits and Product Pipeline

Soybean, corn, cotton, and canola have been the most representative of biotech crops as of today. However, in addition to those four crops, biotech alfalfa, biotech sugar beet, biotech papaya, biotech tomato, biotech sweet pepper, and biotech squash were launched and are now commercially available. For soybean, corn, cotton, and canola, insect resistance and herbicide tolerance have been the traits most frequently integrated into these crops since biotech crops were first commercialized in the United States in 1996. Owing to this, cultivation acreage of the biotech versions of cotton, soybean, canola, and corn share significant portions of global planting area of each crop (Figure 4).

Bt genes targeting several different types of lepidopteran or coleopteran pests (Table 1) and HT genes to confer tolerance to a few herbicides have been effectively used in the locations, where the cultivation of biotech crops has been allowed. In comparison to the *Bt* genes, fewer HT genes have been used in commercialized crops. Tolerance to glyphosate has been most widely used in agriculture up to the present, although glufosinate tolerance and sulfonylurea tolerance have been integrated into some crops.

Agricultural use of Bt and HT traits in crops will continue in the future. Theoretically, insect pests can develop resistance to Bt proteins. IRM has been implemented to maintain the effectiveness of Bt proteins by planting refuge crop acres where non-Bt crop is planted. For example, mating between Bt-susceptible insects from the refuge and potential resistant insects from Bt corn acreage largely ensures that susceptibility of pests to the Bt proteins is inherited by the next generation of pests. In the case of HT crops, emergence of glyphosate

Table 1 Bt proteins in commercial crops

Crop	*Bt protein*	*Event name*	*Target pests*
Corn	Cry1Ab	Bt11 (Syngenta), MON810 (Monsanto)	European corn borer
	Cry1F	TC1507 (Dow AgroSciences and DuPont Pioneer)	European corn borer
	Cry1A.105 + Cry2Ab2	MON89034 (Monsanto)	Lepidopteran pests
	Vip3Aa20	MIR162 (Syngenta)	Lepidopteran pests
	mCry3a	MIR604 (Syngenta)	Corn rootworm
	Cry34Ab1/Cry35Ab1	DAS-59122-7 (Dow AgroSciences and DuPont Pioneer)	Corn rootworm
	Cry3Bb1	MON88017 (Monsanto)	Corn rootworm
Cotton	Cry1F	281-24-236 (Dow)	Lepidopteran pests
	Cry1Ac	3006-210-23 (Dow)	Lepidopteran pests
	Cry1Ac + Cry2Ab2	MON 15985 (Monsanto)	Lepidopteran pests

[a]Bt proteins in stacked event, which were developed by conventional crossing of the events listed above, are not listed in this table. Breeding stacks express the transgenes inherited from parental lines.

Source: Reproduced from CropLife International, 2012a. Labeling of Biotech-Derived Products; CropLife International, 2012b. Plant Biotechnology Pipeline. Available at: http://www.croplife.org/view_document.aspx?docId=3631 (accessed 27.08.12).

tolerance weeds in farmlands has been more frequently reported than before, may be due to the intense use of a specific herbicide in biotech crop fields during the last decade. Emergence of herbicide-tolerant weeds and potential development of Bt-resistant insect pests have encouraged developers to continue developing new *Bt* genes and HT genes (Table 2). For example, a soybean event expressing Cry1Ac to control lepidopteran pests of soybean is at its late stage of global regulatory approvals before commercialization. Additional herbicide tolerance traits such as the tolerance to 2-, 4-D, and dicamba are also under regulatory pipelines. New molecular mechanisms to control insect pests are under development, such as RNA interference, which provides a mode of action different from Bt proteins.

In addition to Bt and HT traits, other traits are also gaining increasing importance because of market needs. For example, a high-oleic acid soybean is in its early stage of market launch in the US; some other crops are in the regulatory pipeline or are in the late stages of product development, awaiting their optimized composition (Table 2). Developing biotech events conferring tolerance to abiotic stress such as drought has been one of the hot topics for key developers in the world. One such product, a drought-tolerant biotech corn, is almost ready to be launched in the market in the Americas.

As of today, most of the biotech crops currently on the market have come from key players located in the US and the European Union (EU). However, it is expected that many new biotech events could be brought to market by developers in other countries in the near future, including India, China, and Latin American countries (Stein and Rodríguez-Cerezo, 2010). In terms of crop types, application of agbiotech is increasing so that more diverse biotech crops are anticipated to appear on the market in the future (Figure 4), such as potato, rice, sugarcane, wheat, and some vegetables (Figure 5). Another phenomenon that will be observed after 2014 is the potential of generics of biotech events, as the early patents on biotech crops expire (Gruskin, 2012).

Safety of Biotech Crops

Before commercialization, the safety of biotech crops has been assessed following internationally harmonized assessment principles prepared by concerted efforts of global experts. Only biotech crops whose safety has been confirmed by authorities of countries both cultivating and importing them have been commercialized. In fact, there have been no reported cases that any of the commercialized biotech crops cause human safety problems or environmental problems up to now. Scientific and regulatory authorities worldwide have clearly stated their views that foods from biotech crops are thoroughly evaluated by comprehensive testing for food, feed, and environmental safety and are as safe as their conventional counterparts. However, the critics continue to have concerns about the safety of biotech products, especially biotech crops. Application of biotech in other areas such as protein drugs and enzymes rarely becomes the subject of safety controversy. Likewise, foods developed by traditional breeding methods, which often involve random changes in nucleotide sequence by crossing or using mutagenic radiation, are rarely the cause of safety concerns. Such inconsistencies might indicate that concerns for biotech crops come from outside the science. The safety of biotech crops should, however, be assessed solely based on science. This section outlines what the scientific assessment for biotech crop safety entails.

Safety Assessment Principles and Concepts Applied to Biotech Crops

The safety of biotech crops was first addressed at the Asilomar Conference on California's Monterey Peninsula in 1975. The potential biohazards and regulation of biotechnology was first discussed at the Conference on rDNA. The scientists at the meeting addressed the safety issue presented by handling rDNA technology and proposed the establishment of guidelines for these experiments to ensure the safety of both DNA recombinant technology and its users. The detailed descriptions of the data to be assessed for safety can vary between countries and government agencies, but the assessment principle and criteria for safety assessment of biotech crop is fairly consistent between the nations. This is the outcome of concerted international efforts to harmonize the risk assessment of foods derived from modern biotechnology (FAO, 2008). Table 3 lists some key international consultations addressing

Table 2 Biotech crops in the pipeline

Crop	*Early development*	*Advanced development (next 5–7 years)*
Corn	*Herbicide tolerance* – Dicamba & Glufosinate (Monsanto) – FOPS (Monsanto) – Multiple mode (DuPont Pioneer) *Insect resistance* – Corn borer III (Monsanto) – New modes of action coleopteran III (DuPont Pioneer) – New modes of action lepidopteran III (DuPont Pioneer) – Second generation corn rootworm (Syngenta) – Novel insect traits (Syngenta) *Nitrogen utilization* – (Monsanto, BASF) – (DuPont Pioneer) – (Syngenta) *Stress tolerance* – Drought tolerance II (DuPont Pioneer) – Second generation drought tolerance (Monsanto, BASF) *Crop composition* – Improved corn feed (BASF) – Increased ethanol (Syngenta)	*Herbicide tolerance* – Roundup® hybridization system (Monsanto) – DHT: 2,4-D & FOP (Dow AgroSciences) *Insect resistance* – Corn rootworm III (Monsanto) – Optimum® Intrasect™ insect protection + Agrisure Viptera™ (DuPont Pioneer) – Lepidopteran/Coleopteran DP 4114 (DuPont Pioneer) *Integrated corn rootworm & European corn borer refuge* – Optimum® AcreMax™ XTreme Insect Protection (DuPont Pioneer) *Stress tolerance* – Drought (Syngenta) – First generation drought tolerance (Monsanto, BASF) *Increased yield* – (Monsanto, BASF)
Soybean	*Insect resistance* – Hemiptera/stink bug (DuPont Pioneer) – Lepidopteran (DuPont Pioneer) *Nematode resistance* – Soybean cyst nematode (Syngenta) – Soybean cyst nematode (BASF, Monsanto) *Disease resistance* – Asian soybean rust II (DuPont Pioneer) – (Syngenta) *Fungal resistance* – (BASF) *Increased yield* – Second generation (Monsanto, BASF) *Crop composition* – Increased oil and improved feed efficiency (DuPont Pioneer)	*Herbicide tolerance* – Dicamba (Monsanto) – Multiple mode (DuPont Pioneer) – Hydroxyphenylpyruvate deoxygenase (HPPD) inhibitors (Syngenta, Bayer CropScience) – DHT: 2,4-D & FOP (Dow AgroSciences) – GlyTol® + HPPD + LibertyLink® (Bayer CropScience, M.S.Technologies) – Imidazolinone (BASF, Embrapa/Brazil) *Insect resistance* – Second generation insect-Protected (Monsanto) – Intacta RR2 PRO® (Monsanto) *Increased yield* – First generation (Monsanto, BASF) *Crop composition* – Soymega™ SDA omega-3 (Monsanto-Solae) – Low saturated, zero trans-fat oil (Monsanto)
Cotton	*Insect resistance* – Lygus Control (Monsanto) *Stress tolerance* – Drought tolerance (Monsanto, BASF)	*Herbicide tolerance* – Dicamba and Glufosinate (Monsanto) – DHT (Dow AgroSciences) *Insect resistance/herbicide tolerance* – GlyTol® + LibertyLink® + TwinLink™ (Bayer CropScience) – Next generation IR + GlyTol® + LibertyLink® (Bayer CropScience) *Insect resistance* – Genuity® Bollgard III (Monsanto)
Canola	*Herbicide tolerance* – Dicamba tolerance (Monsanto) *Increased yield* – First generation (Monsanto, BASF) *Crop composition* – Healthy fatty acids (BASF) – Oil quality (Bayer CropScience)	*Herbicide tolerance* – Next-generation Genuity® Roundup Ready® (Monsanto) – Glyphosate tolerance DP 73496 (DuPont Pioneer) – LibertyLink® tolerance (DuPont Pioneer) – Glyphosate tolerance + LibertyLink® tolerance (Bayer CropScience) – Next-generation Genuity® Roundup Ready® LibertyLink® (Bayer CropScience, Monsanto)
Rice	*Herbicide tolerance* – (DuPont Pioneer) *Insect resistance* – Dual Mode of Action Lepidopteran (DuPont Pioneer) – (Bayer CropScience)	*Herbicide tolerance* – LibertyLink® tolerance (Bayer CropScience) *Crop composition* – Beta-carotene content increased – Golden rice 1 (IRRI/Philippines) – Beta-carotene content increased – Golden rice 2 (IRRI/Philippines)

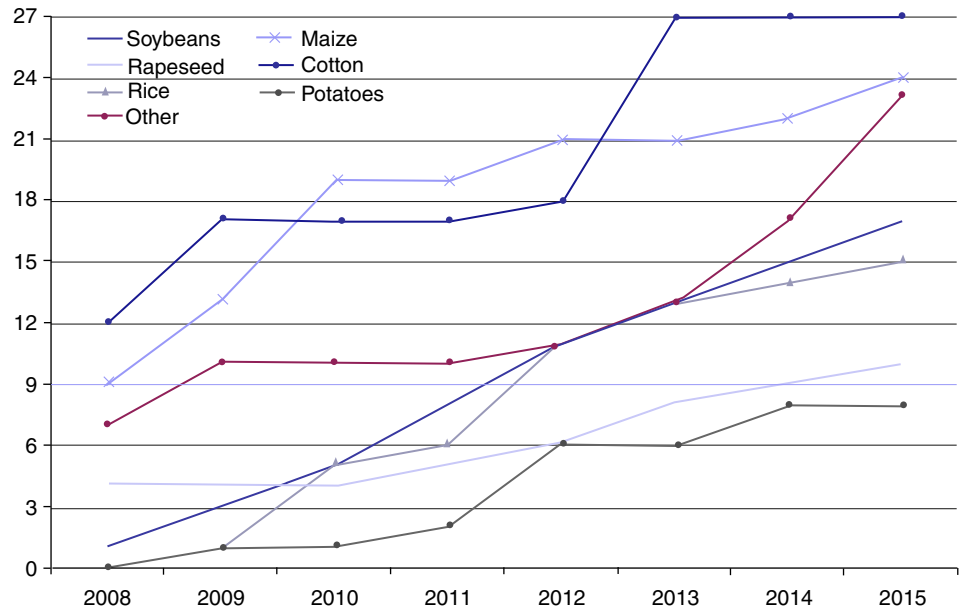

Figure 5 Projected number of events in biotech crops worldwide, by crop. Reproduced from Stein, A.J., Rodriguez-Cerezo, E., 2009. The global pipeline of new GM crops: Implications of asynchronous approval for international trade. Technical Report EUR 23486 EN. Luxemburg: European Communities.

the safety assessment of biotech crops including Food and Agriculture Organization (FAO) of the United Nations, World Health Organization (WHO), Organization for Economic Cooperation and Development (OECD), International Life Sciences Institute, International Food Biotechnology Council, and the Codex Alimentarius Commission (CAC), which have conducted a critical role in the globe.

Comparative Approach and Substantial Equivalency

The goal of the approaches used globally for the safety assessment of biotech crop is to assess whether foods or feeds from a biotech crop is 'as safe and nutritious as' its conventional crops that have an established history of safe use. Conventional crops that have an established history of safe use are considered safe because they are familiar, and not necessarily because of scientific proof. Conventional foods can include hazardous substances, such as endogenous allergens, antinutrients, or toxicants. Other variables not related to the characteristics of the crop can also affect human safety when a food prepared from conventional crops is consumed, such as intake amount, processing methods, physiological characteristics of the specific consumer, etc. Instead, human beings have empirically developed ways to reduce the adverse effects that may come from endogenous food components, such as by cooking, soaking, etc. As a result, a food is regarded safe if "there is reasonable certainty that no harm will result from its consumption under anticipated conditions of use" (OECD, 1993).

Table 3 Some key international consultations addressing the safety assessment of biotech (~2006)

Year	*Organization*	*Title*
1986	Organization for Economic Cooperation and Development (OECD)	Recombinant DNA (rDNA) safety considerations: Safety considerations for industrial, agricultural, and environmental applications of organisms derived by rDNA techniques
1990	Food and Agriculture Organization (FAO) of the United Nations/World Health Organization (WHO)	Strategies for assessing the safety of foods produced by biotechnology, a joint FAO/WHO consultation. Geneva, Switzerland, 5–10 November 1990
1990	International Food Biotechnology Council (IFBC)	Biotechnologies and food: assuring the safety of foods produced by genetic modification. Regulatory Toxicology and Pharmacology, 12, S1–S196
1993	WHO	Health aspects of marker genes in genetically modified plants. Report of a WHO Workshop. Copenhagen, Denmark, 21–24 September 1993
1994	WHO	Application of the principles of substantial equivalence to the safety evaluation of foods or food components from plants derived by modern biotechnology. Report of a WHO Workshop, Copenhagen, Denmark, 31 October–4 November 1994
1996	FAO of the United Nations/WHO	Biotechnology and food safety. Report of a Joint FAO/WHO Consultation, Rome, Italy, 30 September–4 October 1996. FAO Food and Nutrition Paper No. 61
1996	International Life Sciences Institute (ILSI)	ILSI Allergy and Immunology Institute (AII) guidance for assessing the allergenic potential of foods derived from biotechnology
1997	OECD	Report of the OECD workshop on the toxicological and nutritional testing of novel foods
2000	FAO of the United Nations/WHO	Report of a Joint FAO/WHO Expert Consultation on foods derived from biotechnology – Safety aspects of genetically modified foods of plant origin. WHO Headquarters, Geneva, Switzerland, 29 May–2 June 2000
2000	Codex Alimentarius Commission (CAC)	First session of the Codex ad hoc Intergovernmental Task Force on foods derived from biotechnology. Chiba, Japan, March 2000
2001	FAO of the United Nations/WHO	Allergenicity of genetically modified foods, a joint FAO/WHO consultation on foods derived from biotechnology. Rome, Italy, 22–25 January 2001
2001	CAC	Second session of the Codex ad hoc Intergovernmental Task Force on Foods Derived from Biotechnology. Chiba, Japan, March 2001
2002	OECD	Report of the OECD Workshop on the nutritional assessment of novel foods and feeds

Source: Reproduced from FAO, 2008. GM Food Safety Assessment – Tool for Trainers. Rome: Food & Agriculture Organization of the United Nations.

It is not realistic to establish an absolute safety level of foods containing numerous components regardless of the origin of the food ingredients, be they conventional crops or biotech crops. The conventional toxicological approaches to examine the absolute safety of individual chemicals are unrealistic when applied to the safety assessment of biotech foods. Moreover, conventional agricultural practices and the cultivation of conventional crops are not risk free due to the use of insecticides. Therefore, the ecological risk assessment should compare the novel risks associated with the environmental release of biotech crops against the background risk associated with the existing agricultural practice, projected over the expected lifetime of the release (Hayes, 2004).

Risk assessment of biotech foods and food derived from biotech crops relies on comparative analysis, that is, comparison with their conventional counterparts in order to identify intended and unintended differences. Comparative analysis is based on the assumption that conventional counterparts from which biotech crops have been derived are generally regarded as safe to consume, based on the history of safe use. Information on conventional crops serves as a baseline for food/feed and the environmental safety assessment of a biotech crop (concept of familiarity, concept of substantial equivalence, comparative safety assessment). To that end, the most appropriate comparator analysis for biotech crops should have all traits in common except for the newly introduced traits: near-isogenic line of the biotech crop being tested. The concept of substantial equivalence, a safety assessment framework first described in an OECD publication titled 'Safety Evaluation of Foods Derived by Modern Biotechnology: Concepts and Principles' (OECD, 1993), embodies the idea of a comparative approach mentioned above. This document was developed by some 60 experts from 19 OECD countries, who spent more than 2 years discussing how to assess the safety of foods derived from modern biotechnology (FAO, 2008). One important benefit of the

concept of substantial equivalence is that it provides flexibility, which can be useful in the safety assessment of food derived from biotech crops. This concept of substantial equivalence is often used for the safety evaluation of biotech crops as well. It is a tool that helps to identify any difference, deliberate or unintended, which might be the focus of further safety evaluation (FAO, 2008). Science-based risk assessment, case-by-case approach, and step-by-step approach globally being applied to the risk/safety assessment framework for biotech crops were also developed as the outcome of OECD-led efforts.

Safety/Risk Assessment of Biotech Crops

Establishment of substantial equivalence is not an assessment of safety per se. Substantial equivalence is a starting point in the safety evaluation rather than an endpoint of the assessment (Schauzu, 2000; Kuiper *et al.*, 2001). In principle, all organisms and foods derived from organisms include significant levels of nucleic acids. There are no risks inherent in the use of recombinant technologies as all DNA is chemically and structurally the same. Therefore, the concept of risk assessment of biotech crops is based on any functional and chemical changes resulting from the genetic recombination. A new biotech crop is considered to be substantially equivalent to the conventional crop when the levels of nutrients, allergens, or naturally occurring antinutrients are not substantially different and there are no new allergens or toxins. When foods from biotech crops are concluded as substantially equivalent it is not necessary for further safety testing. However, when there is a substantial difference between a biotech crop and its near-isogenic line, such difference has to be subsequently subjected to risk assessment with respect to its potential impact on the environment, safety for humans and animals, and nutritional quality. For example, the newly introduced expression products such as Bt proteins require risk assessment.

Risk is a function of hazard and exposure (risk= hazard × exposure). Risk assessment arose from the need to make informed decisions in a more objective manner. With the help of risk assessment, individuals can make informed decisions about the impacts from their human-based activities on people and society (Nickson and McKee, 2002). Risk assessment, which follows the same deductive logic as basic scientific research, is the process of determining as accurately as possible the actual likelihood and consequences of the risks presented by exposure to identified hazards. Risk assessment should be science-based and transparent, and it requires scientists to organize and evaluate information so that they can evaluate a product's safety in a systematic way. Risk assessment of biotech crops and the foods/feeds derived from biotech crops involves the elements of hazard identification, hazard characterization, exposure assessment, and risk characterization (**Figures 6–8**; FAO, 2010, 2012).

Food safety assessment

For the risk/safety assessment of the foods derived from biotech crops, the CAC has developed several documents. Out of those documents, two are directly related to the safety assessment of biotech crops: principles for the risk analysis of foods derived from modern biotechnology (CAC/GL 44-2003), and guidelines for the conduct of food safety assessment of foods derived from rDNA plants (CAC/GL 45-2003). This guideline document of Codex provides the principles for the assessment of possible toxicity and allergenicity of expressed substances, compositional analyses of key components, evaluation of metabolites, etc. (FAO/WHO, 2006).

Environmental/ecological risk assessment

Problem formulation is the first step in the risk assessment process (**Figures 8** and **9**). The consistency and utility of environmental risk assessment for biotech crops can be improved through rigorous problem formulation (Wolt *et al.*, 2010; CLI, 2005). Assessment endpoints, valued entities that need to be protected, vary depending on the geography due to the difference of the existing wild species in the environment, etc.

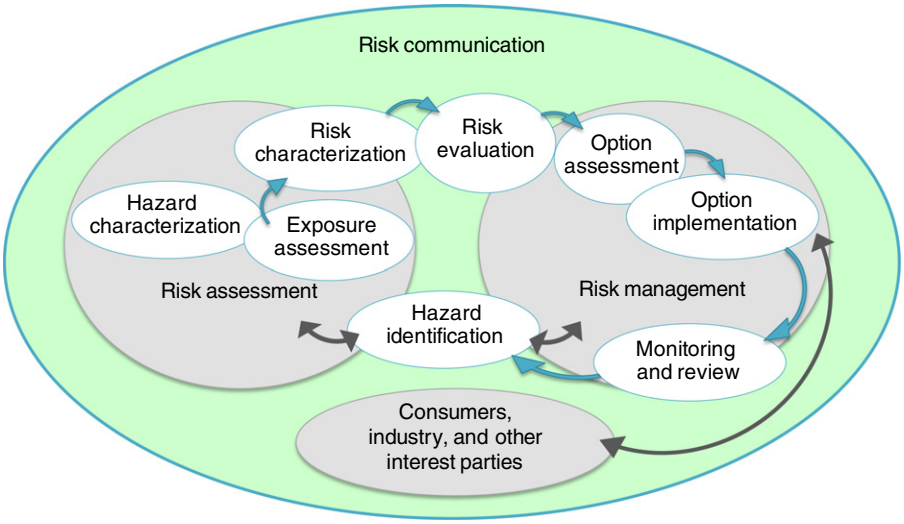

Figure 6 Risk analysis framework for the safety assessment of foods derived from biotech crops. Reproduced from FAO, 2008. GM Food Safety Assessment – Tool for Trainers. Rome: Food & Agriculture Organization of the United Nations.

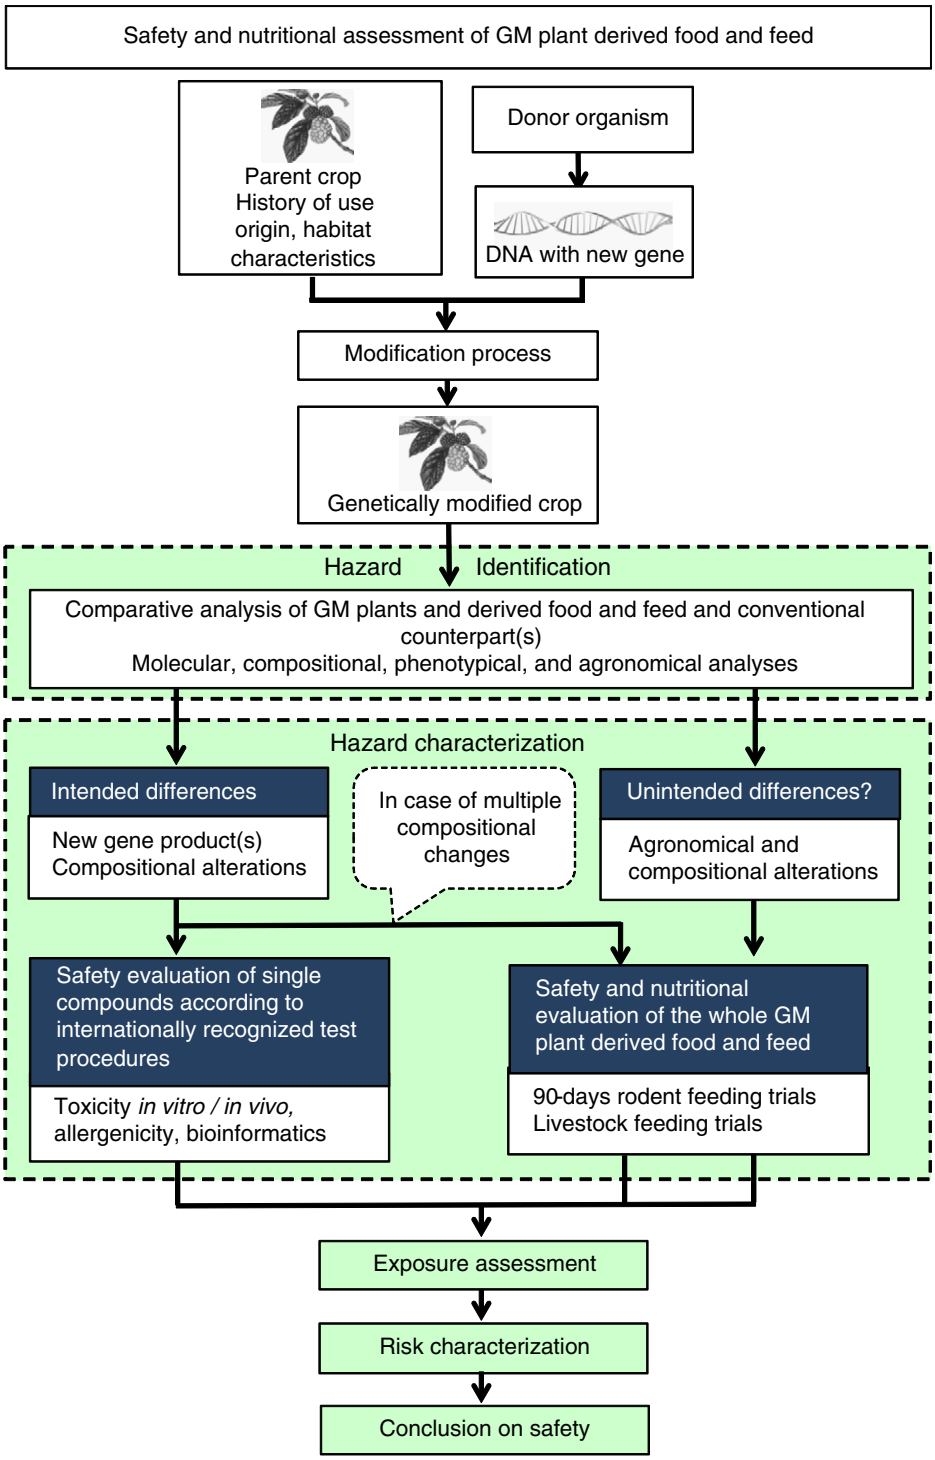

Figure 7 Scheme for premarket safety and nutritional testing of biotech plant-derived food and feed. Reproduced from EFSA GMO Panel Working Group on Animal Feeding Trials, 2008. Safety and nutritional assessment of GM plants and derived food and feed: The role of animal feeding trials. Food and Chemical Toxicology 46 (Suppl. 1), S2–S70.

Therefore, the data to be assessed for environmental risk assessment could vary depending on the environment. For example, interactions of the GM plant with nontarget organisms, plant-to-plant gene flow, weediness potential, etc. can be considered.

Like the Codex food safety guidelines, Annex II and Annex III to the Cartagena Protocol on Biosafety (CPB), especially Annex III, suggest the objective of the risk assessment, general principles, as well as the outline of methodologies. Annex III suggests that the risk assessment should be carried out in a

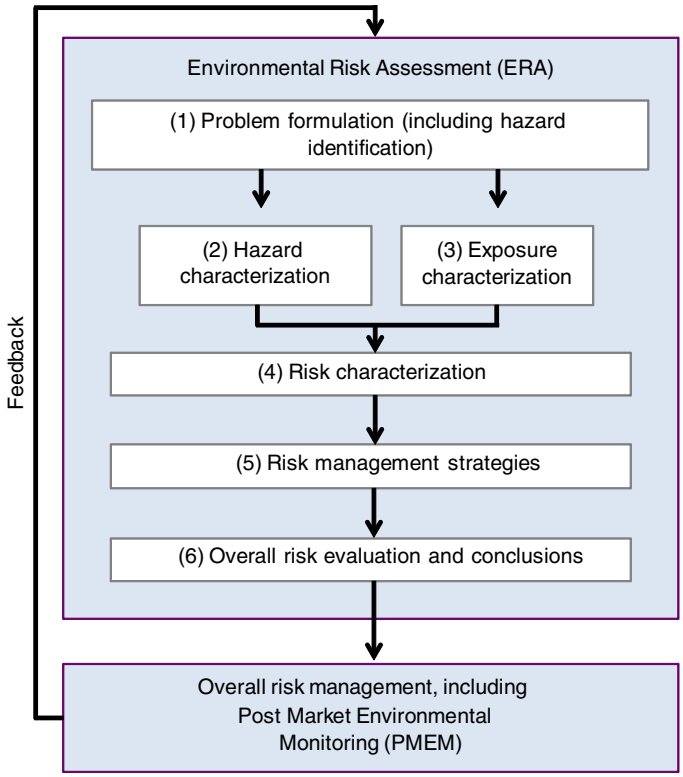

Figure 8 Six steps within the environmental risk assessment. Reproduced from EFSA Panel on Genetically Modified Organisms, 2010. Guidance on the environmental risk assessment of genetically modified plants. EFSA Journal 8 (11), 879.

scientifically sound and transparent manner. At the same time, this protocol also includes words on socioeconomic considerations and precautionary approach. In some countries, it is debatable that science-based risk assessment can be well aligned with socioeconomic considerations and precautionary approach (Raybould, 2010). Socioeconomic uncertainties still remain, and have led in some countries to a continuing emphasis on precaution, which sometimes results in the demand of experimental data less relevant to risk assessment.

Regional and International Regulatory Policy and Instruments on Biotechnology

There are three main elements of international regulations relating to research into, and the trade and use of, GM crops. These are the Codex Alimentarius, OECD consensus documents, and the CPB (FAO and WHO, 2000).

Codex Alimentarius Commission (Codex)

Although there are no specific international regulatory systems, several international bodies are involved in developing protocols for GM crops. The CAC (Codex) is one of them and it is the joint FAO/WHO body responsible for putting together the standards, codes of practice, guidelines, and recommendations that constitute the Codex Alimentarius. The purpose of the CAC is to protect the health of consumers, to ensure fair practices in food trade, and to promote coordination of all food standards work undertaken by international governmental and nongovernmental organizations. The Codex's objectives include consideration of standards, guidelines, or other recommendations as appropriate for foods derived from biotechnology or traits introduced into foods by biotechnology on the basis of scientific evidence and risk analysis. Codex developed principles for the human health risk analysis of GM foods. The principles include a science-based, premarket risk assessment performed on a case-by-case basis, and also an evaluation of both direct effects from the inserted gene and unintended effects that may arise as a consequence of insertion of the new gene. The standards set out by the Codex have been used widely as the benchmark in international trade disputes. Three standards relating to GM crops are (1) principles for the risk analysis of foods derived from modern biotechnology (FAO/WHO Codex Alimentarius, 2003a,b), (2) guidelines for the conduct of food safety assessment of foods derived from rDNA plants (FAO/WHO Codex Alimentarius, 2003a,b), and (3) working principles for risk analysis for food safety for application by governments (FAO/WHO, 2007).

Organization for Economic Cooperation and Development

To address the issues and concerns related to the use of modern biotechnology, the OECD published the guidance book on "Recombinant DNA (rDNA) safety considerations: Safety considerations for industrial, agricultural and environmental applications of organisms derived by recombinant DNA techniques"

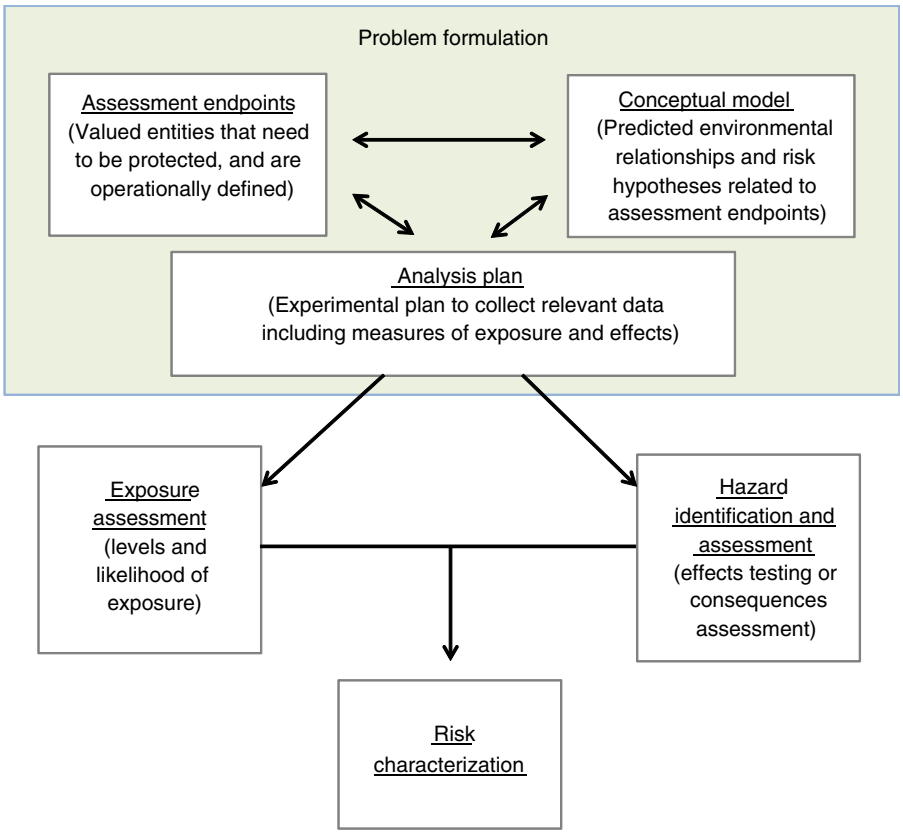

Figure 9 Schematic of problem formulation in the context of the risk assessment process as proposed by the US Environmental Protection Agency. Reproduced from Nickson, T.E., 2008. Planning environmental risk assessment for genetically modified crops: Problem formulation for stress-tolerant crops. Plant Physiology 147 (2), 494–502.

in 1986 called the 'Blue Book' because its cover is blue. This guidance book identified that the "specific aims of rDNA techniques in agriculture are, to reduce vulnerability to environmental stress: to detect and control infectious agents in animals and in the field and postharvest; to reduce dependence on use patterns of chemical pesticides; to decrease dependence on chemical fertilizers and irrigation; and to increase the nutritional qualities of seed, fruits, grains, and vegetables." The book also says that rDNA techniques "represent a development of conventional procedures. They permit precise alteration, construction, recombination, deletion and translocation of genes that may give the recipient cells a desirable phenotype. Moreover, rDNA techniques allow genetic material to be transferred into, and to express in, another organism which may be quite unrated to the source of the transferred DNA" (OECD, 1986). The book has been used as a starting point for countries that need to set up their own biosafety regulation on GM crops. Producing the consensus documents on environmental and food/feed biosafety is one of the OECD's main activities done by the Working Group on the harmonization of regulatory oversight in biotechnology. The objectives of the OECD's working group are (1) to protect the environment, (2) to promote harmonization, while (3) reducing unnecessary barriers to trade. Working group focuses on the safety assessment of GM crops by the development of consensus documents, information dissemination via BioTrack Online, and facilitating regulatory harmonization. Food/feed consensus documents on new crop varieties including soybean, canola, maize, rice, and cotton, etc. were published by Task Force team. These consensus documents are widely used by many scientists throughout the world as an important reference material when they conduct risk assessment for GM crops.

The Cartagena Protocol on Biosafety

Biosafety is one of the issues addressed by the Convention on Biological Diversity (CBD), which was finalized in 1992 at the UN conference and entered into force on 29 December 1993. Modern biotechnology has both positive and negative implications for human health, the environment, and trade. To ensure the safety of biotech products, regulatory regimes began examining the implications of their use. The term Living Modified Organisms (LMOs) is used only in CPB. Biosafety regimes like the CPB tend to stress the risk side rather than the benefits of biotech products. Risks to biological diversity and human health were foreseen when the CBD was negotiated in the early 1990s (Kinderlerer, 2008). After a series of negotiations at the CBD meeting, although concerns on modern biotechnology were raised by many countries, they clearly recognized that "biotechnology also offers new opportunities for global partnerships, especially between the countries rich in biological resources but lacking the expertise and investments needed to apply such resources through biotechnology and the countries that have developed the technological expertise to

transform biological resources so that they serve the needs of sustainable development" (Chapter 16, Agenda 21. UN, 1992). They agreed to establish or maintain means to regulate, manage, or control the risks associated with the use and release of LMOs resulting from biotechnology, which are likely to have adverse environmental impacts that could affect the conservation and sustainable use of biological diversity, also taking into account the risks to human health. To address the issue of biosafety, the development of measures at the national level and the establishment of international legally binding instrument were proposed by CBD parties. After several years of negotiations, the Protocol, known as the CPB to the CBD, was finalized and addressed the transboundary movement of the products of modern biotechnology and ensured that these products would be as safe as possible. The Protocol was adopted in Montreal on January 2000 (Cartagena Protocol on Biosafety, 2000). This international treaty entered into force on 11 September 2003, 90 days after receipt of the 50th instrument of ratification, and currently has 163 member states although many of the countries, such as USA, Argentina, and Canada that currently produce commercial transgenic crops are not members of the CBD (Kinderlerer, 2008; CBD, 2010). The Protocol has the potential to encourage innovation, development, technology transfer, and capacity-building for agricultural biotechnology, while supporting global conservation and sustainable agriculture goals. The Protocol is important because it establishes rules and procedures for the international trade of products of agricultural biotechnology – referred to as LMOs – including products like agricultural commodities, seeds, and research materials in order to protect the conservation and sustainable use of biodiversity. The Protocol requires that exporters of LMOs seek governmental 'advanced informed agreement' before shipping LMOs for intentional introduction into the environment of importing countries. It also requires government decision-making on imports to be based on sound scientific risk assessment and for results of such assessments to be made available through Biosafety Clearing House (CBD, 2000). The Protocol also requires that LMOs be shipped to countries that are Parties to the Protocol, setting of law in their own countries, for contained use, intentional introduction into the environment, or for direct use for food, feed, or processing to be identified in accompanying documentation as specified in the Protocol. Every 2 years, the Parties meet to discuss implementation of the Protocol's provisions. These meetings are called Conference of the Parties serving as the Meeting of the Parties to the Protocol (COP/MOP). The Parties also work in between COP/MOPs to prepare for the discussions and decisions on upcoming meeting agenda items. The sixth Meeting of the Parties will take place 1–5 October 2012 in Hyderabad, India. There are several issues with the potential to impact trade of LMOs, such as (1) risk assessment and risk management, (2) socioeconomic considerations, (3) documentation requirements, and (4) liability and redress (Nagoya-Kuala Lumpur Supplementary Protocol on Liability and Redress) (CLI, 2011).

National Regulatory Framework

The way governments regulate GM foods varies depending on the national and regional situations. In some countries GM foods are not yet regulated. Countries where they have legislation in place focus primarily on assessment of risks for consumer health. Countries that have provisions for GM foods usually also regulate GMOs in general, taking into account health and environmental risks, as well as control trade-related issues such as potential testing and labeling systems. The GMO regulatory systems that countries apply depend on the existing national legislation, their legal systems, and the administrative systems that are in place. UNEP-GEF's (United Nations Environment Program-Global Environment Facility) National Biosafety Framework (NBF) project has been helping underdeveloped and developing countries to establish biosafety regulations and a regulatory framework since early 2000. As of May 2012, a total of 118 countries have completed the majority of development of their NBFs. Their drafts of the NBFs are available online at UNEP (2008, 2012). Immediately after the Asilomar conference, many countries introduced some form of GMO regulation intended to ensure the safe use of the technology. In the USA, for instance, the National Institutes of Health (NIH) produced guidelines that applied to all organizations receiving funding from the USA government (NIH, 2002). These NIH guidelines remain the primary regulatory system for assuring safety in the USA regarding transgenic organisms in containment. For the agricultural use of commercially released GMOs, the US government deliberately chose to use existing agencies and not to change any laws. The US Office of Science and Technology Policy Committee generated the Coordinated Framework for the regulation of biotechnology in 1986 to guide framework for GM regulation (US Department of State, 1999). The USDA works with the Environment Protection Agency (EPA) and the Food and Drug Administration (FDA) to regulate the use of GMOs.

Genetically Modified Organisms Approval in the USA

The US government has played an instrumental role in assuring human, animal, and environmental safety through a rigid review process of all biotech-derived crops. In the US, three federal agencies are primarily responsible for the regulation of biotech crops, and they are involved in reviewing advances in plant biotechnology. Together they provide a coordinated framework to ensure human and environmental safety. The FDA, which oversees food safety and labeling of whole foods and food ingredients; the US Department of Agriculture (USDA), which oversees inspections of GM plants and food stocks, and the EPA, which oversees the registration and regulations of all pesticides, herbicides, and GM crops. Even after the commercialization of any biotechnology product all three regulatory agencies have the legal power to demand immediate removal from the marketplace of any product should new, valid data indicate a question of safety for health or the environment (USGC, 2005).

Food and Drug Administration

The FDA provides voluntary premarket consultations with food companies, seed companies, and plant developers to ensure that biotechnology-derived foods meet the safety standards for safety. Since 1992, the FDA has held the view

that foods from plants produced through modern biotechnology are as safe as those from plants developed through conventional breeding. Therefore, GM foods should be regulated the same as any other foods entering the market. Accordingly, the FDA evaluates the application of biotechnology to food products on a case-by-case basis, as it does with any other food. Under the Food, Drug and Cosmetic Act, the FDA usually focuses on the products, the food, or food ingredients, rather than on the plant development processes used in their production, as the basis for regulation. The same holds true for food and ingredients derived through biotechnology. The FDA offers a series of testing procedures that enable food manufacturers to anticipate safety concerns and to consult with the FDA as necessary for a regulatory review of new plant varieties and products testing under development. The FDA review process focuses on the areas, such as (1) safety and nutritional value of the newly introduced proteins, (2) identity, composition, and nutritional value of modified carbohydrates, fats, or oils, (3) concentration and bioavailability of nutrients for which the food crop is consumed, and (4) potential for allergens to be transferred from one food source to another. To ensure safety, a variety of toxicological and other product safety data are provided to the FDA for food products or ingredients produced through the use of new plant varieties. The FDA requires GMO developers to notify the agency at least 4 months in advance of commercialization of any GM foods or animal feed and supply the food safety authority with their research data for review. In practice, biotech companies have filed notices of commercialization long before the 4-month minimum. The FDA review includes a thorough safety assessment that compares every significant parameter of the GM plant with the traditional counterpart. If no changes are detected, the FDA concludes the GM crop to be substantially equivalent to the conventional crop with respect to nutrition and food safety (USGC and NCGA, 2005).

US Department of Agriculture

The USDA and the EPA are responsible for reviewing the ecological effects of new plants developed through biotechnology. The Animal and Plant Health Inspection Service (APHIS) within the USDA is the primary agency regulating the safety testing of biotech plants that are not insect or disease resistant. APHIS approval must be obtained before proceeding to field test or commercialize a biotech plant. To test a biotech plant in the field, GM crop developers must seek an environmental release permit from APHIS. Once testing is allowed, APHIS and state agriculture officials can inspect the test field throughout the process to ensure that tests are conducted safely. Before GM crops can be grown commercially, a petition must be submitted to APHIS containing the scientific details about the plant, results of field tests, and any indirect effects on other plants. This petition is published in the Federal Register, providing the public time to comment. When the USDA has determined that the product is safe for field use, it is approved for commercialization. There are also four points at which USDA may advance or halt development of a biotech plant product. These are (1) greenhouse approval, (2) field trial authorization, (3) authorization to transport seed, and (4) permission for commercialization (USGC and NCGA, 2005).

Environmental Protection Agency

In addition to APHIS, the EPA also regulates herbicides and has jurisdiction over crops that are insect and disease resistant under the Federal Insecticide, Fungicide, and Rodenticide Act. Environmental exposures to pesticide substances produced in plants are regulated by the EPA to ensure that there are no unreasonable adverse effects on the environment, including nontargeted organisms, such as insects, birds, fish, deer, and other species. The EPA's regulations focus on the pesticide produced by the plant, rather than on the plant as a whole. Such pesticides are subject to registration requirements similar to other pesticides. The agency requires applicants of new plant pesticides to obtain experimental use permits. Before any field testing, EPA officials must review and approve permit plants containing pesticidal properties (USGC and NCGA, 2005).

The European Union

All GMOs need authorization before being placed on the market in the EU. The EU has one of the world's strictest approval procedures for GM products. If, after an extensive scientific risk assessment, the European Food Safety Authority (EFSA), concludes that the product in question is as safe as a comparable non-GM variety, a political decision needs to be made whether or not to authorize the product. This decision-making phase is administered by the EU Commission and involves the member states. The EU legislation requires the EU Commission to stick to the following timelines: upon reception of a positive EFSA opinion, the Commission has 3 months to bring about a vote of the Standing Committee. Once the Standing Committee has voted, if the member states do not achieve a qualified majority for or against the approval, the Commission has to submit the approval dossier to the Appeal Committee within 2 months at the very most. In exceptional circumstances, the Commission may agree with the applicant to align regulatory procedures (EuropaBio, 2012). **Figure 10** shows how EU approves GM food and feed.

Obtaining Approval to Market Genetically Modified Organisms in European Union

Unlike the US, where existing regulations were applied to regulate biotech product, the EU made new regulations to handle the safety of biotech crops. For example, Directive 220/90/EEC relating to experimental releases and marketing of GMOs was entered into force in 1990. With the considerable advances in GM and after substantial revisions, Directive 90/220/EEC was replaced by Directive 2001/18/EC in 2001 to ensure that the regulations of GMOs would meet the demands of EU regulators and consumers. Directive 2001/18/EC on the deliberate release of GMOs into the environment outlines the principles for, and regulates, experimental releases and the placing on the market of GMOs in the EU. Council Directive 90/220/EEC contains the procedures relating to approval of

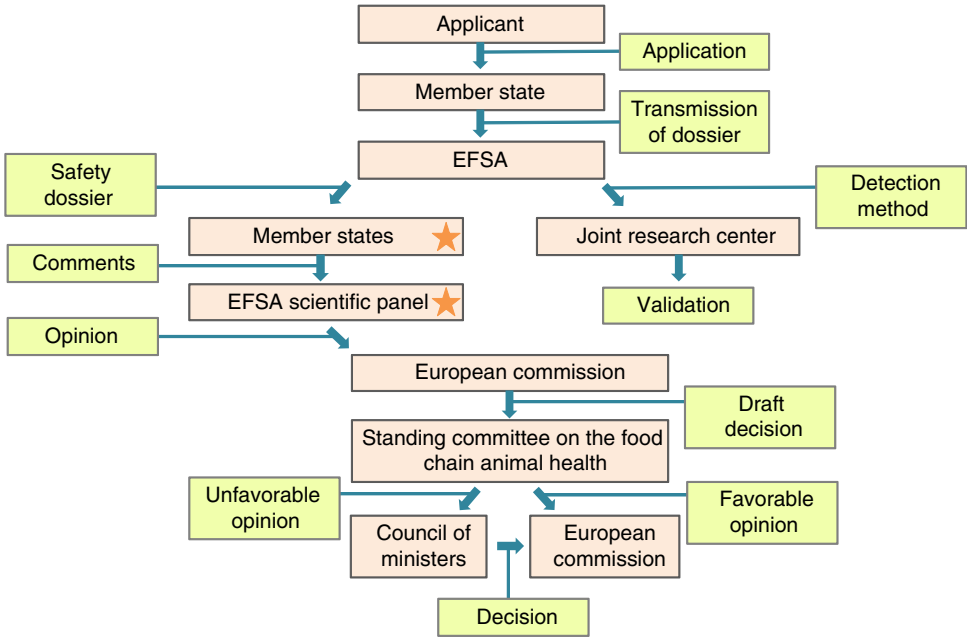

Figure 10 EU approval procedure for GM food and feed. EFSA, European Food Safety Authority. Reproduced from Kleter G., Kuiper, H.A., 2006. EU Regulatory Framework and Status of Genetically Modified Crops. EAAP Workshop. ERIKILT Institute of Food Safety, Wageningen.

the deliberate release of GMOs into the environment for research and development and for placing the GMO on the market (European Commission, 2012a,b; EFSA Panel on Genetically Modified Organisms, 2010). Any person seeking approval to place a GMO on the market must submit a notification to the competent authority of the member state where the product is to be placed on the market for the first time. The notification dossier must describe the risk analysis conducted, show that the products comply with the relevant European Community product legislation, and must describe the environmental risk assessment required by the Directive. The notification also must include specific conditions of use and handling and a proposal for labeling and packaging, which should comprise at least the requirements stipulated in Annex III of the Directive, as amended. On receipt of the notification, the competent authority has 90 days to either forward the notification dossier to the Commission with a favorable opinion or inform the applicant that the proposed release does not fulfill the requirements of the Directive. After receiving a notification dossier, the Commission immediately forwards it to the competent authorities of all member states. If no objections are raised by the competent authorities of the member states within 60 days of the Commission forwarding the notification dossier, then the competent authority that received the notification shall issue a written consent to the applicant and shall inform the other member states and the Commission of that consent. (Maurer and Harl, 1998). Besides the above-mentioned several EU Directives on GMOs, there is a Regulation (European Commission (EC)) 1829/2003 on genetically modified food and feed in the EU to ensure a high level of protection of human health and welfare, environment, and consumer interests, while seeking functioning of the internal market. The Regulation is supplemented by Regulation (EC)1830/2003 to handle traceability and labeling of GMOs placed on the market.

The European Food Safety Authority

The main objectives of the regulations on GM food and feed in EU are (1) to protect human and animal health by introducing a safety assessment of the highest possible standards at the EU level before any GM food and feed is placed on the market, (2) to have in place harmonized procedures for risk assessment and authorization of GM food and feed that are efficient, time-limited, and transparent, (3) to ensure clear labeling of GM food and feed in order to respond to consumers' concerns and enable them to make an informed choice, and to avoid misleading consumers, and (4) to set labeling requirements for GM feed which provide farmers with accurate information on the composition and properties of feed, thereby enabling them to make an informed choice.

The EFSA is the key scientific body of the EU to implement risk assessment regarding food and feed safety. In close collaboration with national authorities and in open consultation with its stakeholders, EFSA provides independent scientific advice and clear communication on existing and emerging risks. EFSA was set up in January 2002, as an independent source of scientific advice and communication on risks associated with the food chain. EFSA was created as part of a comprehensive program to improve EU food safety, ensure a high level of consumer protection and restore and maintain confidence in the EU food supply. In the European food safety system, risk assessment is done independently from risk management. As the risk assessor, EFSA produces scientific opinions and advice to provide a sound foundation for

European policies and legislation and to support the EC, European Parliament, and the EU Member States in taking effective and timely risk management decisions. EFSA's activity covers food and feed safety, nutrition, animal health and welfare, plant protection, and plant health. Regarding the GMO risk review, EFSA's Panel on GMOs provides independent scientific advice on the safety of GMOs, such as plants, animals, and microorganisms on the basis of Directive 2001/18/EC on the deliberate release into the environment of GMOs and GM food and feed, and also on the basis of Regulations (EC) 1829/2003. As shown in **Figure 10**, the EFSA's Panel conducts risk assessments in order to produce scientific opinions and advice for risk managers. Its risk assessment work is based on reviewing scientific information and data in order to evaluate the safety of a given GMO. This helps to provide a sound foundation for European policies and legislation and supports risk managers in making effective and timely decisions. The Panel carries out much of its work in the context of authorization applications, as all GM food and feed products must be evaluated by EFSA before they can be authorized in the EU (EFSA, 2012). The Panel works independently, transparently to deliver timely scientific advice of the highest standards to support the policies and decisions of risk managers. The Panel carries out its work either in response to requests for scientific advice from risk managers or on its own initiative. It frequently sets up working groups involving external scientists with relevant expertise to focus on specific matters and help produce scientific opinions. For any GMO and derived food or feed to be authorized in the EU, a company must submit an application for authorization on placing on the market in line with European legislation. In accordance with EU legislation, an independent scientific risk assessment is to be carried out by the GMO Panel. The Panel's independent scientific advice is then used by the Commission and member states when taking a decision on market approval (EFSA, 2012).

Labeling of Genetic Modification Foods and Consumer Choice

The issue of labeling the food products containing biotech ingredients is one that has been debated at length by both national governments and international standard-setting bodies for many years (CropLife International, 2012a,b). Whether or not to require labeling of GMO is a key issue in the ongoing debate over the risks and benefits of food crops produced using biotechnology. Those in favor of labeling emphasize on the consumers' rights to know what is in their food. Opponents of labeling point out the expense and logistical difficulties of labeling and the fact that no significant differences have been found between GMOs and conventional foods. The issue of labeling GM foods is a complex one that has yet to be resolved. What is clear, however, is that some kind of labeling policy will be adopted by most countries. Right now, the decision to label GM products is not so much related to the actual safety of the product, but rather to the fear associated with such products. The presence of a GM label should not imply that the product is less safe or is significantly different from conventional foods as all GM foods have to meet the safety standards before being approved for placing in the market for sale. The only way to develop and maintain a labeling system that is truthful, not misleading, and verifiable is to ensure that it is based on objective criteria, such as the actual composition of the food, and not on the method of manufacture. (ISAAA, 2004; Caswell, 2000; McHughen, 2001). Consensus among global regulatory bodies on the need for and potential implementation of biotech labeling regimes has been attempted via the CAC – the international food standards setting body established by the UN FAO and the UN WHO. In July 2011, after 20 years of negotiation, Codex adopted a text that does not endorse mandatory labeling; instead the text explicitly states that "any approach implemented by Codex members should be consistent with already adopted Codex labeling provisions." It also clearly states that there is no intent "to suggest or imply that foods derived from modern biotechnology are necessarily different from other foods simply due to method of production." In addition to the work at the international level through Codex Alimentarius, numerous countries have implemented their own domestic rules relating to labeling of foods containing biotech ingredients. Although domestic labeling rules vary considerably, they tend to fall into two categories: mandatory or voluntary labeling. More than 40 countries, including Australia, Brazil, China, India, Russia, Japan, Spain, and the UK, require genetically modified foods to be labeled. These countries have mandatory labeling laws that specify clear rules that must be followed when food products are known to contain biotech ingredients. Other countries, such as Canada and the US, have put in place voluntary labeling frameworks. Labeling regulations around the world differ widely in their scope, labeling exceptions for certain types of ingredients and degree of enforcement. Because of these differences in approaches, a food product with biotech-derived ingredients that must be labeled in one country does not necessarily have to be labeled in another country. Consequently, the observed effects of these policies on consumer choice, consumer information, food marketing, and international trade also vary significantly (CropLife International, 2011).

Canada

In Canada, special labeling is required for all foods where safety concerns, such as allergenicity and compositional or nutritional changes are identified. Labeling must indicate the nature of the change and must be understandable, truthful, and not misleading. Manufacturers can choose to label products to provide information regarding the presence or absence of GM ingredients, so long as the information is factual and neither misleading nor deceptive (ISAAA, 2004).

United States of America

In the USA, all foods must be labeled when there are health concerns, differences in use or nutritional value, or where the common name no longer adequately describes the food derived from the GM plant. In January 2001, the FDA released a Draft Guidance for the Industry: Voluntary Labeling. The document provides guidance to manufacturers in the

appropriate, truthful, and nonmisleading labeling of foods and provides examples of acceptable and unacceptable labeling language (ISAAA, 2004). The US FDA currently requires labeling of GM foods if the food has a significantly different nutritional property; if a new food includes an allergen that consumers would not expect to be present (e.g., a peanut protein in a soybean product); or if a food contains a toxicant beyond acceptable limits. Early in 2001, the FDA proposed voluntary guidelines for labeling food that does or does not contain GM ingredients. USA has a view that mandatory labeling would only be required if a product has been significantly changed nutritionally or if there have been changes in health-related characteristics (CropLife International, 2011).

European Union/United Kingdom

The new EU labeling regulation requires that any food containing GM ingredient or derivative in the amount more than 0.9% will have to be labeled. GM animal feed will also have to be labeled but products of animals fed GM feed, like milk, meat, and eggs, are not required to be labeled. Since 1997, EC regulation on labeling requires that the products intentionally containing GM ingredients must always be labeled, whatever be the level of content. The new regulation extends the range of products requiring traceability and labeling by including derived products – those with ingredients derived from a GM source that are not identifiable by analysis – as well as products consisting of or containing GMOs. Labeling is required for vegetable oils and other highly refined products where the genetically modified DNA or the resulting protein is no longer present or detectable in the final product. Adventitious presence (AP) of GM ingredient no higher than 0.9% requires no labeling (ISAAA, 2004).

Japan

Japan's Ministry of Agriculture, Forestry, and Fisheries (MAFF) is responsible for environmental safety approvals, feed safety approvals, and biotech labeling for foods. On 1 April 2001, MAFF established a labeling scheme that requires labeling for biotech food products if the biotech DNA or protein can be scientifically detected in the finished foods. MAFF regulations require labels for rDNA only if an ingredient is at least 5% of the total weight of the product (ISAAA, 2004).

Korea

The Korea Food and Drug Administration is in charge of inspecting GMO labeling on processed foods that use GM corn, soybean, or soybean sprout, or when these three goods are among the top five ingredients of a processed food product. Minor ingredients are exempt from labeling requirements. The threshold level of unintentional mixture of GMO to those three ingredients is 3%. Korea's Ministry for Food, Agriculture, Forestry and Fisheries also requires labeling for commodity shipments of the three goods if the shipment is destined for direct consumption and if it contains a biotech-enhanced component of 3% or higher. Identity Preservation handling certificate is required for no labeling. Revision of labeling is underway that requires all food, and any ingredients, directly produced from a GMO must be labeled, even if this GMO is undetectable in the final product (ISAAA, 2004).

Implications of Labeling Food

Labeling of GM foods does not advance consumer health information. Before entering the food supply, GM foods and ingredients must be approved for food safety by the national regulatory approval process. All scientific information to date supports the view that there are no health or food safety concerns with products derived from biotechnology. Food labels are often considered one way to support consumer choice and allow for differentiation of products in the marketplace; however, governments considering the implementation of labeling systems must carefully weigh the need to provide necessary and accurate safety information with the additional costs associated with labels that include marketing claims and nonhealth-related information. A study in Canada showed that labeling costs could be equivalent to at least 9–10% of the retail price of processed food products, and 35–41% of the producer prices. The study also concluded that GM and non-GM foods labeled as 'GM free' would be equally affected by this price increase, which amounts to US$700–950 million per year in Canada (KPMG Consulting, 2000). The costs include (1) farmers needing to segregate grains; (2) silos needing to be extremely careful about when they take deliveries to keep GM grains separate; (3) food processors needing to test shipments and so on down to the food chain. For any labeling provisions to be enforceable in relation to GM foods, they should be supported by reliable, validated methodologies for detecting the presence of transgenic protein or DNA. Workable labeling threshold levels for the presence of biotech-derived material in food, feed, and food ingredients are needed to facilitate accurate and truthful labeling. Labeling requirements should be science-based to give consumers meaningful information about the foods they buy and eat. Developing labeling regulations outside these scientific principles distracts attention from the legitimate health, safety, and nutritional issues related to food products. Mandatory GM food labeling provisions are costly to consumers, producers, and governments and can unnecessarily inhibit the development of innovative technologies to help feed a growing global population (CropLife International, 2012a,b).

Costs of Regulatory Compliance

The regulatory approval process for new GM crops is said to be slow and expensive, causing enormous burden to the developers who want to use this new technology to commercialize the biotech products. In fact, estimates of the compliance costs for the full regulatory approval of a GM crop are not available; as such information has been regarded as confidential by the developers of the biotech products. All GM crops are subjected to a series of full safety assessment and regulatory scrutiny during the developments of GM crops. Cost categories, for example, for insect-resistant maize include various experiments and tests, such as molecular characterization,

compositional assessment, animal performance and feeding studies, protein production and characterization, protein safety assessment, nontarget organism studies, agronomic and phenotypic assessments, enzyme-linked immunosorbent assay development, validation and expression analysis, environmental fate studies, toxicology tests, and so on. The compliance costs vary from one regulatory submission of safety documents to another with differences in the number and type of field trials, analytical tests, bioinformatic analysis, animal studies, and other comparative safety assessments, which are basically determined by the target crops, novel trait introduced, number of countries engaged in regulatory approvals, and the type of regulatory approval. Kalaitzandonakes *et al.* (2007) analyzed the compliance costs for insect-resistant maize and for HT maize. A range of costs incurred were estimated to be US$6 180 000–12 510 000 for HT maize, and a range of US$7 060 000–15 440 000 was estimated for insect-resistant maize. In this study, R&D costs were not included and if the indirect costs stemming from the unnecessary and unexpected regulatory delays are considered, the estimated compliance cost might go up. Falck-Zepeda *et al.* (2012) also estimate the cost of compliance with biosafety regulations in developing countries in a range of US$100 000–1.7 million. A recent study by Phillips McDougall (2011) showed (**Table 4**) that the overall cost to bring a new biotech trait to the market between 2008 and 2012 is on average US$136 million. The highest costs were associated with the discovery stages with the aggregated cost of US$31 million, followed by genetic sequence construct optimization procedures with a cost of US $28.3 million. However, collectively the costs of meeting regulatory requirements including testing and registration amounted to US$35.1 million, occupying 25.8% of total costs. A total cumulative time required to complete each stage of activities is approximately 11 years, presenting the longest time for registration and regulatory affairs of 65.5 months.

On the basis of the results of the survey into the actual time associated with each activity stage of the R&D process, the overall time involved in regulatory testing and approval appears to have increased. If this trend is real and continues it could have a significant effect on the cost of regulatory testing and authorization in future years. The results of McDougall's study are indicative of the costs and timelines required to discover, develop, and authorize a new plant biotechnology trait in a large-scale commodity crop, along with the associated import market approvals that are necessary for such a crop to enter the global grain trade, for example, maize, soybean, rapeseed, or cotton (Phillips McDougall, 2011). The compliance costs incurred by GM crop developers appear to be quite high. This can partly be attributed to the shrinking of development and commercialization of new GM crops. Agbiotech innovation and product development have recently slowed down, and high compliance costs for regulatory approval have been cited as one of the key constraints. One example that excessive regulation hinders the release of biotech crops for humanitarian purposes is the Golden Rice case. Ingo Potrykus, who developed provitamin A-enriched Golden Rice, pointed out that overly regulated, unjustified, and impractical legal requirements are stopping genetically engineered crops from saving millions from starvation and malnutrition. He pointed out that genetically engineered crops could save many millions from starvation and malnutrition if they can be freed from excessive regulation. The crop was stalled for more than 10 years by the working conditions and requirements demanded by regulations, including field test permission and safety data collection to satisfy the National Biosafety Authority (Potrykus, 2010; Fedoroff, 2011).

Emerging Issues

AP of biotechnology-derived materials in commodity shipments of grains, oilseeds, and their processed products remains a significant trading issue between the trading partners. It is critical to enable global bulk commodity supply chains to function effectively and efficiently. The term low-level presence (LLP) refers to a specific instance of AP. LLP is the adventitious presence of biotechnology-derived plant material in imported commodities that has completed a full safety assessment and has been approved for use in food, feed, grain, and derived products by the safety authority in one or more countries, including the country of cultivation. Under current bulk-handling systems for grains, there are many opportunities for crops to commingle during crop production, transportation, conditioning, and storage. Although many countries have zero tolerance for unapproved biotech products, LLP in GM crops is currently unavoidable. There are four different cases of

Table 4 Discovery, development, and authorization costs, and time of a plant biotechnology product

Category	*Cost ($ million)*	*Duration in months*
Gene discovery	31.0	46.7
Construct optimization	28.3	32.8
Commercial event production and selection	13.6	34.0
Introgression breeding and wide-area testing	28.01	42.0
Regulatory science	17.9	47.0
Registration and regulatory affairs	17.2	65.5
Total	136.0	268.0

Source: Reproduced from Phillips McDougall, 2011. The cost and time involved in the discovery, development and authorization of a new plant biotechnology-derived trait. A Consultancy Study for CropLife International. Midlothian, UK: Phillips McDougal.

unapproved biotech products that may be found in the food/feed supply. These are the cases where (1) biotech products that have received safety clearance for some use (e.g., feed) but not for others (e.g., food), (2) biotech products that have been approved for all possible uses in one or more countries but not yet in others, a case of asynchronous approvals, (3) experimental GMOs contained in laboratories, greenhouse, or field trials, which are found in the commercial food/feed supply chain, and (4) biotech products that have been reviewed but may have expired (Government of Canada, 2011). In consideration of the potential cases of LLP with structural asynchronicity, biotech industry, governments, and academia have realized in recent years that it may cause grain trade disruption as the biotech pipeline moving toward or awaiting regulatory approval has expanded, whereas regulatory approvals across different countries have become less synchronized. To actively handle any potential food/feed safety or environmental risks from the LLP of unapproved biotech products, some countries have developed their own national LLP policies which they can implement when the need arises. For instance, the Philippines is drafting 'guidelines of LLP risk management' by the formal adoption of Codex annex on LLP into their own policy. International organizations have also sought to facilitate the development of national LLP policies. In 2008, the Codex Alimentarius Task Force on Foods Derived from Biotechnology provided an international guidance for food safety assessment of biotech events authorized as safe for food and feed in one or more countries, including in the country of cultivation, but not yet in the country of import. Details on guidelines are described in the Annex on food safety assessment in situations of LLP of rDNA plant material in food. The Annex foresees that importing countries can undertake a simplified risk assessment in instances of LLP of products that have been fully approved in the country of export in a manner consistent with Codex risk assessment guidelines. Parallel efforts to develop guidelines for supporting environmental risk assessment have also been advanced by an OECD Working Group for the Harmonization of Regulatory Oversight in Biotechnology in the last few years. The OECD Working Group is preparing a technical review for the environmental risk assessment of LLP in seeds and commodities that can function biologically as seeds (International Food & Agricultural Trade Policy Council, 2011). With the increase in the global development of GM products, LLP situations are expected to increase, thus requiring a global approach for LLP. Therefore, it is important for all countries to review their LLP policies to work together to find an effective strategy for managing LLP. There will be a growing need to develop global strategies to manage LLP and to ensure continued and unimpeded trade of grains. When assessing a future LLP policy, several considerations should be taken as follows: (1) ensuring the safety of food, feed, and the environment, (2) minimization of unnecessary trade disruptions, (3) administrative efficiency, transparency, and predictability, (4) promotion of agricultural innovation, and (5) consistency with international guidance on LLP, such as the Codex guidelines, OECD, and FAO/WHO recommendations. As global demand for commodities continues to rise – and biotech crops increasingly produce much needed grain – it will be critical that trade policies support the uninterrupted flow of agricultural and food products to stabilize food supplies and reduce food price volatility. Although new biotech-derived crops will enable farmers to better cope with the effects of climate change, improve resource-efficiency, and increase yields, each new product also raises the potential for trade disruptions due to asynchronous approvals and concerns over the LLP of agbiotechnology products approved in the country of cultivation but not yet in the country of import. To prevent jeopardizing global food security, countries must immediately work toward solutions and exchange policies that minimize the risk to trade that stems from LLP situations. Increasing awareness of the impact of trade policies (or lack of policies) related to LLP, as well as encouraging synchronized approvals and the implementation of LLP policies will be essential to meeting this growing world's food supply demand supported by plant biotechnology. (Lukie, 2011; OECD, 2012).

Conclusion

Since the first commercialization of GM crops in 1996, in countries where GM crops are grown and widely consumed, there have been no reports of them causing any significant environmental damage or human health problems such as toxic, allergenic, or nutritionally deleterious reaction. It is due to the fact that robust scientific tests on GM crops before commercialization have been conducted and that the combination of testing by developers to meet regulatory requirements for safety clearance has been done. Extensive use around the world over a longer period of time with large exposed populations, and the absence of evidence of harm, does provide important proof of safety of GM crop. GM crops have been tested for 30 years, grown commercially for 16 years, and they have been proven safe and reliable as food and for the environment. There have been no cases of GM crops causing ecological harm or human health problems following 16 years of their cultivation and commercialization. The recent report from the EU that involved 25 years of research from 500 independent research groups concluded that GM crops are no more dangerous than other crops and are as safe as crops produced by conventional plant breeding. The EU, the Royal Society, and the US National Academy of Sciences all conclude that GM crops are safe and effective. If GM technology had not been available to the 14 million farmers using the technology in 2009, maintaining global production levels at the 2009 levels would have required additional plantings of 3.8 million hectare of soybean, 5.6 million hectares of corn, 2.6 million hectares of cotton, and 0.3 million hectares of canola. This total area requirement is equivalent to approximately 7% of the arable land in the US, or 24% of the arable land in Brazil (Brookes *et al.*, 2011). Furthermore, GM crops have reduced pesticide use by 390 million kg. GM crops are not the problem, but part of the solution to sustainably feeding 9 billion people. However, despite the fact that GM crops have many advantages to solve world hunger and poverty, there also exist groups who are less convinced, insisting that new technologies have limitations always bringing uncertainties and generating new gaps in knowledge. Strategies that could increase the efficiency of biosafety regulation without burdening GM crop developers with further unnecessary bureaucracy need to be established. There is a clear need for scientific communities to

do more research in a number of areas in biosafety research so that GM crop developers make good decisions in terms of new crop design and target plants, and also to develop products that meet wider consumer needs. The general view of the scientists is that the risks to human health and the environment are very low for GM crops; however, GM crops do present certain potential challenges in risk management. The situation may prove to be more challenging in the future, depending on the crops developed. There is a need to continue to develop safety-assessment technologies to keep pace with the advancement of GM crops with new traits.

Problems that are currently faced with in regard to GM crop regulation is that 'sound science' basis is not properly observed and applied in many countries; instead, most biosafety regulations are based on perceived risks rather than on real risks. The resulting unpredictable and less functional regulatory system causes delays in the approval of new crops. Even the creation of regulatory systems that demand extensive assessment followed by a lengthy decision-making process do more to serve as barriers to trade and new crop development than they do to ensure safety for consumers. It is very important to maintain a global, innovation-friendly regulatory environment – one that is predictable, functioning, transparent, and guided by good science. Science-based and globally harmonized regulation is the most effective way to ensure that farmers have the choice of the best available technologies to help them meet their own agricultural needs in a sustainable way. As new applications of biotechnology are evolving rapidly, regulatory requirements and guidelines also must be able to adapt quickly and applied using on a case-by-case principle. It is fair to say that there is no case where there exists a 100% risk-free situation. Therefore, it is important to have a balanced view on the risks and benefits of GM crops.

Breeding: Animals

GL Bennett, EJ Pollak, LA Kuehn, and WM Snelling, USDA, ARS, US Meat Animal Research Center, Clay Center, NE, USA

Published by Elsevier Inc.

Glossary

Deoxyribonucleic acid (DNA) sequence Ordered sequence of the DNA nucleotides adenine (A), cytosine (C), guanine (G), and thymine (T). An animal's genome is its complete DNA sequence.

Effective population size Number of animals in an ideal population that would result in the same genetic diversity as an actual, usually much larger, population.

Genetic effects (additive, dominant, recessive, and overdominant) These terms describe the phenotype of the heterozygous genotype compared to the phenotypes of the two homozygous genotypes. When the heterozygote is equal to the average of homozygotes, equal to the smaller homozygote, equal to the larger homozygote, or exceeds the larger homozygote, then gene effects are called additive, recessive, dominant, or overdominant, respectively.

Genetic evaluation A prediction of the genetic value of an animal as a parent. Genetic predictions are used to predict average phenotypic differences between progeny from different parents.

Genotype A genotype describes which form of a particular polymorphism an animal has. An animal with two copies of one form is homozygous and an animal with one copy of each form is heterozygous.

Heterosis The difference in the phenotype of crossbred animals compared to the average of the purebreds used to make the crossbred.

Inbreeding coefficient Estimate of the proportional increase in DNA nucleotide pairs that have identical ancestral origin due to using related parents compared to a base population.

Permanent and residual environment Residual environment is the nongenetic proportion of differences between contemporary animals. Permanent environment describes nongenetic differences that are repeatable over time and repeated measurements.

Phenotype A characteristic or trait of an animal such as weight, milk production, litter size, or hair color.

Polymorphism A difference in DNA sequence among animals. Polymorphisms can be nucleotide sequence changes (e.g., AGG or ACG), deletions of nucleotides, or other differences.

Brief History of Breeding Livestock

Breeding and selection of animals probably began with domestication. Genetic changes in livestock occurred well before herders, shepherds, and caretakers understood genetics or the processes of evolution. Robert Bakewell, an eighteenth-century Englishman and influential livestock breeder, promoted the concepts of breeding to be the best, evaluating breeding animals relative to his concept of an ideal animal, and using inbreeding to fix desired traits. These concepts eventually led to identifying and recording parentage of animals, the formation of breed societies that kept pedigrees and set standards for animals considered as members of the breed, and either deliberate mild inbreeding in breeds and strains or unintentional inbreeding due to a limited number of parents available.

Motivation for Selection

The movement toward development of breeds and strains with pedigreed animals lacked a strong scientific basis. However, the diversity created among breeds and the availability of multiple-generation pedigrees fueled the application of scientific breeding in the twentieth century. Application of the principles of Mendel, mathematics of genetics and evolution, and objective measurements by livestock breeders is making steady and sometimes rapid genetic changes in animal traits and products important to livestock production and consumers.

Although livestock breeders accelerated genetic change, many also shifted from a goal of an ideal animal to emphasize other outcomes. These outcomes often included profit, income, and cost of livestock production. Livestock breeders more closely examined what traits affected income and costs. Usually, examination identified a need for including more animal and product traits in the description of income and costs and in the traits needing genetic evaluation. Some livestock industries integrate breeding through product marketing segments under a single ownership or cooperative. Integration often leads to broader definitions of selection goals compared to owners involved in a single segment of the multisegmented industry. Product pricing schemes can play a role in livestock breeders' selection goals for segmented industries. Payment for milk fluid volume or milk protein sends profit-oriented signals from milk processors through commercial dairy producers to dairy cattle breeders and encourages measurement and genetic evaluation of different milk traits. Appropriate pricing of products can cause livestock breeders to make selection decisions beneficial to their industry even though it could otherwise not be beneficial to their industry segment.

Other desired outcomes of selection are the control or elimination of genetic defects; reduced incidences of disease, parasites, parturition difficulty, and lameness; improved animal well-being through adaptation to management and to the ambient environment; and reduced effects of animals on the

environment. Livestock breeders whose main business is the sale of breeding animals may choose to emphasize traits that differentiate their animals from those of competitors. Many livestock breeders face the dilemma of wanting to simplify their breeding programs while improving the genetics of many traits. Selection to improve some traits might result in negative changes in other traits. Simple approaches to selection may hide negative effects in traits not considered for selection.

The selection index is one of the methods of distributing selection among several traits to predict a desired selection outcome. In its simplest form, the selection index multiplies predictions of genetic differences for several traits by index weightings and sums the products for each animal. Breeders use the index rather than individual trait genetic evaluations. Objectively defined, profit-driven indexes weight traits according to economic values reflecting incremental changes in costs and returns. Subjective weights and constraints can alter economic indexes to address traits that are difficult to value economically like animal behavior. Other weightings of traits can result in proportional genetic changes among traits or preventing genetic change in one or more trait whereas other traits do change.

Modern Genetic Theory and its Adoption

Breeding animals begins with a decision to continue with a current population of animals or to replace part or all of it with new breeds or lines. Region, country, climate, management, prevalent diseases and parasites, product types, import restrictions, and history influence popularity and choice of breeds and lines. For some species and places, livestock producers used the same breeds over long periods, but in other species and places they often changed the breeds. The predominant breed for dairy cattle production is Holstein in many countries with temperate climates. Commercial egg production depends on selected lines developed from Leghorn chickens. Beef cattle, swine, and sheep producers use many breeds to adapt to regional and marketing differences.

Beef cattle, poultry, and swine make wide use of crossbreeding. Crossbreeding uses two or more breeds or lines and can make use of divergent breeds resulting in less focus on a single breed. For beef cattle breeders this lack of focus on a single breed has often led to creating new breeds by combining existing breeds.

Following the choice of a breed or crossbreeding system, livestock breeders make genetic changes by selecting animals that are different from average and use them as parents. A single equation, often referred to as the breeders' equation, captures many features of livestock selection. The equation for genetic change measured in units of genetic standard deviations per year is simply intensity of selection times accuracy of the genetic evaluation at selection divided by age of the parents when progeny are born (intensity $\times$ accuracy $\times$ time^{-1}). Although simply stated, the components are interrelated. Changing one often changes another.

Each livestock species and type of product present a different set of potential changes for intensity, accuracy, and time. These sets of potential changes explain why livestock breeders implement different selection programs for each species. Breeders of livestock producing milk and eggs often rely on progeny information resulting in higher accuracy genetic evaluations, moderate selection intensity, and older parents. Breeders of livestock emphasizing growth in young animals can use information on the parents resulting in less accuracy, more intensity, and younger parents.

Advances in technology alter potential changes for intensity, accuracy, and time. These advances can increase genetic change per year and can lead to changes in the design and operation of selection programs. Reproductive technologies can change intensity of selection by increasing the number of progeny per parent, increase accuracy of genetic evaluation by producing more closely related animals, and decrease parental age by allowing more rapid replacement of parents. Advances in measuring animals can increase accuracy by reducing errors, by making repeated measurements possible, and by adding traits not previously available for genetic evaluation. Measurements modified for use on younger animals can result in earlier selection. Genetics and genomics technology can increase accuracy and allow selection at younger ages.

Selection programs consist of four pathways: sires of males considered for selection, dams of these males, sires of females considered for selection, and dams of these females. These pathways often have different intensities, accuracies of selection, and ages of parents. Intensities of selection for parents of males considered for selection are usually higher than for parents of females and males not considered for selection. Analyzing these pathways guides evaluation and choice among selection programs.

Documenting Genetic Change in Livestock

Livestock breeders made large changes in animals over a long time. Selecting European pigs during the twentieth century resulted in a 90–100% increase in growth rates and a 60–70% decrease in backfat thickness, but little change in litter size (Merks, 2000). Changes in growth rate and backfat thickness accelerated in the second half of the century with greater specialization and adoption of new genetic evaluation technology. Broilers representing 2001 commercial strains weighed 4 times those of strains representing 1957 broilers when fed a 2001 diet and 3.5 times as much when fed a 1957 diet (Havenstein *et al.*, 2003b). Yield of breast meat averaged 20.3% for 2001 broilers versus 11.9% for 1957 broilers (Havenstein *et al.*, 2003a). Comparisons of 2001 and 1957 broilers on 2001 and 1957 diets show that genetic changes are responsible for most of the performance changes. Flock and Heil (2002) reported increase of one-third for eggs laid and a decrease of one-third in feed consumed per weight of egg laid during 24 years of testing commercial laying hens in Germany. Genetic trends in Holsteins show milk yield more than doubling from 1957 to 2010 (Animal Improvement Programs Laboratory website). Rates of genetic change for important traits now exceed 1% annually in many livestock species. In addition to broad genetic changes in the livestock industries, experimental selection demonstrated large genetic changes in many common or uncommon traits like resistance to facial eczema, a disease in sheep (Morris *et al.*, 1994), and increased twinning in cattle (Gregory *et al.*, 1997). Genetic changes in

some of the uncommon traits point to possible future expansion of the definition and goals for livestock selection.

Technology and Organization of Modern Selection Programs

Electronics

Accurate information is paramount to successful selection programs. Information vital to the genetic evaluation supporting these selection programs consists of individual animal identification, pedigree information, and phenotypes. Estimates of the accuracy of the individual's predicted breeding merit complement genetic evaluation results. This accuracy is predicated on the assumptions of the model used to create the predictions of merit being the correct model and on accurate information being recorded. Electronic capture of animal identification and phenotypes improves the integrity of the information contained in the national datasets used for genetic evaluations.

Electronic identification such as Radio Frequency Identification (RFID) equipment, ear tags and ear tag readers, allow livestock producers to scan the identification of an individual directly into a recording system; hence, eliminating the potential errors of human recording. Phenotypic information can often be collected at the same time and hence automatically collated with the identification of that individual. Misidentification or inaccurate association of phenotypes to individuals compromises the precision of the evaluation. Accuracy is a statistical result based on the assumptions of a correct model and errorless information, whereas precision is a concept that relates to the validity of these assumptions.

In some cases, electronically collected data may also be more accurate than the same data appraised by humans. Electronic scales calibrated to obtain weights at stability can be more accurate than the same weights recorded by the person watching the scale. Instrument grading of carcasses for quality measures (e.g., marbling score) is objective and more accurate than visual appraisal for the same measurement.

Electronic transmission of information to central databases expedites the process of data entry into the genetic evaluation database. Previous methods depended on data being transcribed and mailed to central locations and finally entered manually into the database with iterations of checks to validate the integrity of the information. Electronic transmission of digital data allows for immediate submission, electronic queries of the data to check for errors (e.g., data outside of acceptable ranges), and direct database query of the information to ensure consistency of new data with data entered previously into the database (e.g., sex of the individual). Electronic searches of the database provided via the web allow access to genetic evaluation information immediately on creation. Electronic distribution of files of evaluations directly to the owners of the animals speeds up the process of selection. Finally, highly computerized systems of data capture, validation, and synthesis lend support to more frequent genetic evaluations that in turn provide more timely information for selection decisions earlier in an animal's life. An example of frequently run genetic evaluations is the American Angus Association® genetic evaluation that runs weekly (Angus genetic evaluation website).

DNA Technologies

Application of DNA-based technologies for livestock improvement starts with on-farm collection of animal tissue samples. Those samples are then transferred to a laboratory, where DNA is extracted for genotyping and the genotypes are interpreted to provide the livestock breeder with information for selection and mating decisions. Any tissue containing DNA is a possible sample. Blood and hair follicles are common DNA sources for cattle. Ear notches and tips of tails are convenient to collect when processing piglets at birth. Sampling systems must ensure cleanliness and avoid contamination with foreign material and DNA from other animals. It is vital that the system maintains identity of the sample so that DNA-based information corresponds to the animal that was sampled (e.g., creation of a DNA sample collection website). Some systems use prelabeled sample containers and barcoded tissue sampling ear tags. These types of systems use the same identification for sample and animal tag and can reduce labeling errors to maintain consistency between animal and sample identity.

Collection and processing of DNA samples must occur before making decisions. One of the uses of DNA information is identifying genetic defects. Decisions on a carrier animal (one normal DNA copy and one mutated DNA copy) and its parents can occur any time between birth and use as a breeding animal. Information from animals sampled and genotyped soon after birth allows quick use of information in the parents. In purebred animals, breed associations often post identities of carrier and related animals and indicate their carrier status on pedigrees for a few mutations that are verified and important to the breed. DNA sequencing of animals reveals many mutations at very low frequencies that could adversely affect animals if they had two copies of the mutated DNA. Reporting and transmitting DNA mutation information needs to evolve so that livestock breeders can consider many more mutations.

Determination of parentage is a growing use of DNA testing. In many cases, the livestock producers know the mother at birth but the sire might be any one of a group of sires. Results of parentage from DNA tests returned to livestock producers have different formats. Identification of the most likely parent and its reliability is useful to livestock breeders.

Genetic evaluation systems based on phenotypes require parentage. The parent–progeny connection allows progeny phenotypes to contribute to genetic evaluation of parents and also allows parent information to contribute to genetic evaluation of the progeny. For breeding animals, parentage information is critical for either avoiding inbreeding or creating inbred animals. Parentage determined from DNA samples collected soon after birth allow undelayed incorporation of progeny phenotypes into genetic evaluations.

Livestock breeders receive results of early genetic tests based on DNA several ways. Results can consist of actual DNA differences, predicted effects of DNA differences, and categories of predicted effects. Current tests use many DNA differences and

breeders may receive a predicted value based on them. Genetic evaluation service providers also may directly capture DNA test results and incorporate with other phenotypic and pedigree information. DNA tests can occur any time after an animal is born and information should be entered into genetic evaluation systems at the same time. Electronic transmission and modern inventory and tracking systems help maintain fidelity of information across breeders, providers of DNA tests, breed associations, and providers of genetic evaluations in industry-wide genetic evaluation schemes.

Reproductive Technologies

Reproductive technologies have a tremendous effect on the rate of genetic change in domesticated livestock species. Primarily, most of these gains occur because of increases in the number of progeny possible per individual. Examples of these technologies are artificial insemination (AI) and multiple ovulation embryo transfer (MOET). However, adoption rates of some other reproductive technologies are not only less than AI but they also have the potential to increase rates of genetic change.

Cattle producers have had commercial access to AI since the 1940s, with the establishment of standard procedures and organization of AI cooperatives (Foote, 2002). The use of semen extenders, technology to freeze semen and maintain viability, and the ability to divide a single ejaculate into multiple inseminations has overall increased the utility of AI. As of 2010, the percentage of US dairy cows bred by AI exceeds 60%. Other domesticated livestock species, especially swine and poultry, also heavily use AI although the viability of frozen semen is less than it is in cattle. Difficulty with depositing semen through the cervix of ewes has limited the use of AI in sheep though many large international flocks use laparoscopic techniques.

Similar to AI, MO*Et* allows a female to produce more offspring than would be possible using natural service breeding schemes. For this process, the female is superovulated (using a follicle stimulating-like hormone) and then inseminated. Recovery of fertilized embryos occurs before implantation. These embryos are placed in recipient females to produce calves from the donor female. Cryogenically freezing these embryos adds more options for using them. Shipping frozen embryos to multiple locations or delaying their transfer is possible. In general, cost decreases the use of MOET compared to AI. It is also difficult to identify genetically superior females before using MOET because females have few progeny to prove their genetic merit.

For sex-limited traits, such as milk production, both AI and MOET offer advantages to most of the components of the breeder's equation. More progeny increases the accuracy of selection for the parents. For example, dairy bulls have hundreds of daughters tested for milk production using AI. The larger number of progeny increases selection intensity as fewer sires (AI) or dams (MOET) are needed to produce the next generation of breeding animals. MOET can decrease the generation interval because a bull and a cow are more likely to produce progeny to replace themselves from their first mating. Not surprisingly, both of these advances have had their greatest impact on livestock species with low prolificacy.

Several other reproductive technologies can also increase the rate of genetic change per year in the breeder's equation. Two of these technologies are sexing semen and cloning.

It is possible to sex semen because X-containing sperm have approximately 4% more DNA content than Y-containing sperm (Seidel, 2012). As a result, semen can be sorted into highly probable Y-containing sperm (male) and X-containing sperm (female) using laser-based cell sorting and a fluorescence measure of DNA content. Some possible economic and selection advantages from using sexed semen in dairy and beef cattle production are as follows: (1) increased production of bulls to progeny test more quickly in dairy breeding operations decreases generation interval, (2) increased production of females for milk evaluation from the resulting males in dairy breeding herds increases accuracy of selection, (3) production of heifer calves to replace females in fewer matings, and (4) increasing desired sex ratio in herds designed to produce either replacement bulls or cows for crossbreeding (Hohenboken, 1999). This final application is particularly useful when breeding females with a different type of male. The technology is far from mature due to decreased fertility, high costs, and the time required to sort semen for sex differences (Seidel, 2012).

Cloning in the form of zygotic splitting has been possible in mammals since the mid-1980s. More recently, and with much publicity, somatic-cell nuclear transfer was developed to clone animals from adult donors (Wilmut *et al.*, 1997). Both of these technologies have the potential to affect genetic change. However, the advent of nuclear transfer procedures opened up the potential to clone an animal with a known phenotype and a less well-known genetic potential. Still cloning may offer some advantages in the breeder's equation. Van Vleck (1999) offered some possibilities such as improving dairy progeny testing by cloning the best performing cows to reproduce the cow population and by the selection of cloned progeny. General improvement in accuracy or intensity of selection is possible by balancing the testing of clones with selecting from a limited parental pool. Owing to the costs associated with successful nuclear transfer clones, these gains may not offset current costs of cloning. Additionally, predicted increases in accuracy of selection may be less if performance of clones does not completely reflect natural conditions due to transfer to a recipient female.

Communication and Presentation of Genetic Evaluations

Genetic evaluations provide information for selection; hence ideally, the most recent information would be included in the evaluation of an animal at the time of a selection decision regarding that individual. For species with national programs for genetic evaluation, this scenario could be difficult to achieve for all producers involved in that national program. For example, seasonal breeding of a species (e.g., beef and sheep) focuses on the timing of selection for prebreeding. However, even among species where seasonal breeding is predominant, in large geographical regions such as the United States, the timing of breeding can vary by several months. Year-round breeding programs (e.g., dairy and swine) require frequent access to information to ensure inclusion of updated information.

Historically, national and international associations providing genetic evaluation services to their membership published annual or biannual evaluations. Constraints on more frequent evaluations were data collection and reporting, computing capacity to run the large evaluation programs, and time needed to assemble the results in a publication form (e.g., a sire summary). Interesting nuances peculiar to some traits also challenged the incorporation of new information. For example, producers record and report a dairy cow's monthly performance or a hen's weekly egg count but the trait of interest is total lactation production (the accumulation of all monthly production records) or yearly egg production. Yearling weight may be the trait of interest at weaning but at the time of selection all that is available are correlated birth and weaning weights. Lactation projection strategies based on partial records (using available monthly records of a lactation in progress to predict total production) and multiple trait evaluations capturing information from correlated traits are just two examples of strategies designed to improve the timeliness of evaluations for these situations.

As electronic reporting of data became routine and organizations moved to electronic delivery of genetic evaluation results along with or instead of publications, the timeliness of evaluations improved. Web-based programs allow producers to search and obtain genetic evaluation information online to expedite this process (e.g., Angus sire search and Holstein search websites). These searches allowed producers to identify animals that meet specifications in traits of interest quickly.

As computing capacity and electronic movement and access to information improved, the opportunity to provide more frequent evaluations became possible. For example, the American Angus Association provides weekly runs of genetic evaluations. Another strategy used is to provide interim evaluations that evaluate information from a particular producer alone instead of running the entire national program at the time the information is received. Updates of interim evaluations occur when the national program runs.

Awareness and interest regarding the value of genetic information increased in the animal industries, and so did the desire to record and report evaluations for many more traits. For example, at the Angus sire search website breeders can search the database of evaluations for eighteen individual traits. Efficient selection based on individually considering this plethora of traits is difficult. An alternative to considering individual traits is combining the information into indices designed to reflect selection objectives. At the Angus sire search website, one could search the database for animals that excel in indices (expressed as dollar values) for predicted value at weaning of calves, to feedlots, or the value at harvest of the progeny of an animal considered for selection. The dollar value prediction of calves at weaning is an index consisting of 4 of the 18 individual traits reported:

1. Birth weight – influences difficulty during birth and calf survival hence percent calf crop weaned;
2. Weaning weight – influences revenue;
3. Maternal milk – influences weaning weight hence revenue; and
4. Mature cow size – reflect maintenance requirements and hence expense.

The poultry industry began using indices of up to 16 traits for selection in the 1950s (Kashyap *et al.*, 1981). The presentation of information in the form of indices not only expedites the process of identifying animals that are superior for the function targeted by the index but also more accurately combines information on the traits going into the index leading to more accurate selection decisions for the targeted application. Use of predicted index values of possible future progeny makes it easy to decide the pairing of selected males and selected females.

Selection among Breeds and Lines

Diversity among breeds and lines within breeds makes rapid genetic changes in herds and flocks of livestock possible. A change in breed or line is a one-time event with potential for making important adjustments to the genetic base of a herd or flock. However, forming new breeds is not a sustainable approach to continued genetic change.

Breed and Line Formation

Geographical isolation, political boundaries, natural selection for adaptation to the environment, and selection by humans played roles in forming breeds. Breed formation by crossing existing breeds and interbreeding the crossbreds continues today as livestock breeders attempt to combine desirable and moderate undesirable aspects found in different breeds.

The process of forming and propagating breeds necessarily restricts the available number of potential parents that meet the specifications for inclusion in the breed. Typically, many livestock breeders want to maintain high relationships in an even smaller group of animals and ancestors that are influential and sought after in the breed. The genetic relationship between two animals probabilistically describes the shared DNA. Example relationships are 0.5 for parent and a progeny or for two progeny from the same parents, 0.25 for a grandprogeny and a grandparent, and 0.25 for any two progeny sharing a single parent.

Some livestock breeders intentionally mate related animals to maintain even higher relationship to influential ancestors through both sire and dam. Mating related animals results in inbred progeny. Inbreeding coefficients probabilistically describe the proportion of DNA nucleotide pairs with identical parental DNA origin. Inbreeding coefficients of progeny are one-half of the relationship between the parents. Examples of progeny inbreeding values are 0.25 for parent–progeny mating and 0.125 for mating any two progeny sharing a single parent.

Inbreeding also occurs unintentionally over time. Many generations of repeated emphasis on a few animals of every generation cause most animals to have some shared distant ancestry. This results in progeny with low levels of inbreeding that increase over time. Parents with many progeny contribute little more to a population's diversity than parents that produce a few progeny. A concept called effective population size describes the genetic size and diversity of a breed. Effective population size estimates the number of unrelated parents needed to create the same diversity as found in an actual

population that has related parents, some who produce many progeny. Even in breeds with tens of thousands of animals, the effective size may be a few hundred or less. Smaller effective sizes result in larger increases in unintentional inbreeding. McParland *et al.* (2007) estimated an effective number of 75 for the more than 200 000 Holstein-Friesian dairy cattle born in Ireland in 2004. Most long-established breeds fluctuate in popularity and numbers throughout their history. The introduction of breeds into new areas and countries may consist of importing a few hundred animals or less. When numbers are low (called a bottleneck), effective numbers are reduced further and have a lasting effect on unintentional inbreeding in the breed.

Inbreeding increases the proportion of DNA that is identical in paired chromosomes (homozygous). Homozygous DNA increases the predictability of progeny. Some livestock breeders use inbreeding with the objective of producing more uniform and predictable animals. However, inbreeding increases the proportion of homozygous DNA with undesirable effects as well as desirable effects. Inbreeding itself cannot increase desirable homozygous DNA without increasing undesirable homozygous DNA. Inbreeding often reduces reproductive success of parents, vigor of offspring, and growth (inbreeding depression).

Following the early twentieth-century scientific and commercial successes of hybrid corn created by crossing inbred lines, livestock geneticists hypothesized that simultaneous inbreeding and selection might overcome the detrimental effects of inbreeding alone. An expected advantage of inbred lines is increased variation among the inbred lines compared to variation within the original, preinbred breed. Results of many experimental inbred lines developed into different livestock species demonstrated that selection usually could not overcome the undesirable effects of inbreeding on reproductive success and vigor. Inbred lines in low prolificacy species often failed to sustain the line due to low reproduction and survival. Still, a few mildly inbred lines survived and contributed toward improving some breeds (e.g., Line 1 Hereford; MacNeil, 2009). New genomics technologies may enable creating inbred lines with simultaneous selection of desirable homozygous DNA and elimination of undesirable homozygous DNA.

Breed Comparisons

Breeds and lines within breeds arose from different base populations with different selection histories, effective sizes, and are often not farmed or raised together. Unbiased estimates of trait differences are important for deciding how to use breeds and lines. Governments, livestock organizations, international aid organizations, and companies compare breeds and lines for the benefit and education of livestock producers and for internal use and merchandising by companies. The number of breeds and lines compared and the duration of comparisons vary considerably. Some organized comparisons extended for more than 50 years.

Methods to compare breeds and lines depend on many circumstances. The best approach samples the breeds so that they represent the genetics that are available to livestock producers fairly and accurately. Management, environment, nutrition, disease and parasite prevalence, and marketing can all influence comparisons. Usually, conditions that are representative of most livestock production result in the most relevant comparisons. When production occurs in widely different conditions, it may be desirable to compare breeds and lines in more than one set of conditions.

When comparing well-established breeds and lines, one approach is to sample young animals or fertilized eggs, bring them to a common location, and rear them together. Although conceptually simple, some problems can occur. Broad sampling of many animals with low genetic relationships will likely involve many producers. This situation can cause logistical and timing problems, especially when different breeds tend to be in different regions. Effects of different pretest maternal and offspring management may last into the test period and pretest exposure to some diseases may result in more resistance or susceptibility during the test. If any of these or other pretest conditions are different among breeds, then breed differences on test could partially reflect pretest conditions.

Another approach is to sample animals from breeds and lines and use them as parents in a common location. Progeny from these parents are then born and reared together. Comparisons are free of pretest influences but this type of comparison usually requires more resources and time to complete.

Creating new breeds and lines or importing existing ones into a new country or region can make broad sampling of females for testing impractical. Other situations can make sampling and assembling females for testing difficult such as sampling a breed from a large geographical area. In addition, the use of some breeds and lines is mostly as sires of progeny for harvest and the performance of reproducing females is unimportant. In cases like these, sampling sires from different breeds and lines and breeding them with an unrelated population of females can estimate one-half of the differences among them. Keeping daughter progeny for breeding can estimate one-half of the differences in female reproduction.

Crossbreeding Systems

Breeding males and females of the same breed, called straight breeding or pure breeding, is one way to use breeds and lines. Breeding males of one breed with females of another breed is crossbreeding. Many livestock production systems benefit from planned crossbreeding systems. The benefit is derived from two factors known as heterosis and complementarity.

Heterosis has a genetic basis and describes the difference in performance between crossbred animals and the average of the purebreds used to create the crossbred. Several causes of heterosis are possible and not exclusive. Many studies of heterosis in livestock point to dominance as the primary cause but experiments designed to estimate heterosis often have difficulty separating dominance from other possible causes such as epistasis, the effects derived from combinations of two or more differences in DNA. Dominance occurs when DNA at the same location on a chromosome is not identical among animals and those with pairs of nonidentical DNA perform differently from the average of those with identical pairs

of DNA. If dominance causes heterosis, then heterosis is the sum of dominance at many different pairs of nonidentical DNA.

In some ways, crossbreeding and heterosis are the mirror images of inbreeding and inbreeding depression. Crossbreeding and inbreeding both manipulate the proportions of homozygous and heterozygous DNA, inbreeding by increasing homozygosity and crossbreeding by decreasing heterozygosity. One interpretation of heterosis is that it recaptures the accumulated inbreeding since the breeds separated genetically. Partially, heterosis values can differ among breed crosses because breeds separated at different times and have different genetic histories.

Proportional or percentage differences describe the magnitude of heterosis. Low values are near zero, moderate values are 5% or 10%, and a high value is 15%. Heterozygosity of a cross between two breeds is similar for DNA affecting most traits but levels of dominance and therefore levels of heterosis are different. Traits with low, medium, and high heterosis occur in the same cross of breeds and can be measured in or attributed to sire, dam, or progeny. Generally, heterosis for product (egg, meat, milk, and wool) quality traits is low; it is moderate for growth and feed efficiency; and is moderate to high for reproduction and survival. Heterosis for cumulative traits (e.g., a beef cow's lifetime calf production) is often high.

Many different systems of crossbreeding are possible. One factor in deciding among systems is the expected heterosis expressed in sires, dams, and progeny. Expected heterosis depends on the probability of pairing DNA from two different breeds. Multiplication of this probability by estimated heterosis results in expected heterosis.

Three broad types of crossbreeding systems are rotations, terminal crosses, and composites. Comparisons of crossbreeding systems for heterosis utilization usually report proportions of maximum heterozygosity and therefore maximum heterosis. Maximum heterozygosity occurs when two unrelated breeds are mated together to produce a progeny, dam, or sire. A two-breed rotational system mates sires of one breed with dams of a second breed to produce first-generation progeny. Sires of the second breed mated with first-generation progeny produce the second generation. Sires rotate between the two breeds each generation. After several generations, expected proportion of heterosis is 2/3 for dams, 2/3 for progeny, and 0 for sires. If the rotation is expanded to 3, 4, or 5 breeds, then the expected proportions of heterosis are 6/7, 14/15, or 30/31. Rotational systems replace dams from the progeny and do not need an additional source of breeding females.

Another crossbreeding system taking advantage of heterosis is composite formation. Formation of composites begins with creating crossbreds with a desired breed composition and then using them as parents of the next generation. Progeny from the first generation become parents of the next generation and this continues in future generations. Expected heterosis depends on the number of breeds and their proportions in the initial crossbreds. If the initial crossbreds consist of equal proportions of 2 or 4 breeds, then expected proportions of heterosis are 1/2 or 3/4 in later generations. Expected proportion of heterosis in a composite composed of 1/2 of one breed and 1/4 each of two other breeds is 5/8. Composites need large effective population sizes to limit inbreeding and loss of heterozygosity. Composite formation is also a method of creating new breeds by bringing together desirable traits from different breeds and eliminating most of the inbreeding from the contributing breeds.

The simplest terminal system mates sires of one breed with dams of another breed and sells all progeny for harvest or production. In this system, progeny express 100% heterosis but sires and dams express none. In addition, replacing breeding females from another source within or outside the enterprise is a cost to include in evaluating terminal systems. Variations on the simple terminal system use crossbred dams and crossbred sires. These variations not only increase expected heterosis in dams and sires but also increase complexity of the mating system.

A thorough evaluation of crossbreeding systems includes differences in the value of the breeds as well as expected proportions of heterosis. Adding more breeds to rotational or composite crossbreeding systems not only increases heterosis but can also decrease the average value of the breeds used. Progeny and dams in rotational and composite systems have the same breed proportions averaged across generations. Terminal systems have the opportunity to use breeds that excel in maternal traits as dams and breeds that excel in production and product traits as sires of progeny used for those purposes. Complementarity is the term used to describe the ability to take advantage of breeds' strengths in maternal and sire roles. These specialized breed roles in crossbreeding systems also allow for selection within the breeds to enhance their value for the role.

Genetic Evaluation Using Phenotypes

Components of Phenotypes

Genetic evaluation is the process of predicting an animal's value as a parent. Given a choice between two animals to use as a parent, genetic evaluation predicts the average difference between their progeny and the reliability of that prediction. Livestock breeders can then use these predictions of progeny differences for many different traits to select parents.

Phenotypes are basic pieces of information for genetic evaluation. Phenotypes are measurements, counts, and observations of animal characteristics. Animal weight, carcass length, fat thickness, muscle area, and volume of milk produced are examples of phenotypes measured by scales, rulers, and other devices on a continuous scale with many possible values. Eggs laid in a year, pigs born in a litter, number of inseminations per cow, and lambs produced during a ewe's lifetime are examples of counting phenotypes. Presence of horns and hair color are observational phenotypes.

Partitioning phenotypes (P) into components is the first step in genetic evaluation. The simplest partition is two components, genetics (G) and environment (E), or $P = G + E$. The traditional term for the nongenetic component is environment. However, environment does not mean just weather or housing in the context of genetic evaluation. Environment is really everything that appears to cause variation in phenotype but is not genetic. It is the residual phenotype after accounting

for genetics, E = P − G. This can include measurement errors, random interactions with other animals, and an accumulation of minor events in the animal's life.

Repeated measurement of a phenotype throughout the life of an animal can lead to a second level of partitioning. Some repeated phenotypes are milk yield from different lactations of a dairy cattle and litter sizes from different parities of a sow. The same genetic component repeats each time but some of the environment components may also be long lasting and repeated. The simplest way to account for this is to partition the residual (environmental) component into a long-lasting component, traditionally called the permanent environment (PE), and a temporary component (E). The phenotype now consists of genetic, permanent environment, and temporary environment, P = G + PE + E. Two measurements of the same animal repeat the same genetic and PE components but have different temporary environments.

Mothers can affect the phenotypes of their suckling progeny, especially phenotypes like weaning weights measured in young animals. The amount of milk produced by the mother is one maternal factor but general maternal care and the uterine environment are other possible factors affecting progeny. The mother's genetics (GM) may affect any of these factors. A simple partitioning of phenotype affected by maternal genetics is to sum an animal's genotype, mother's genetic effect, and the residual (environment): P = G + GM + E. The animal's genetic component (G) is known as the direct genetic component when both animal and maternal genetics affect a phenotype. The residual component (E) actually consists of two components: maternal residual and calf residual. For some traits like weaning weight, considering the long lasting (PEM) and temporary parts of the maternal residual component is important. Temporary maternal and temporary calf residual components are indistinguishable and combined into a single residual component (E). Components of weaning and preweaning phenotypes usually considered are animal and maternal genetics, long-lasting maternal residual, and temporary residual: P = G + GM + PEM + E. Two animals born to the same mother in different years have the same maternal genetic and long-lasting maternal environment components and share half of the direct genetic component inherited from their mother.

Ascribing phenotypic values of 15 000 kg of milk or 200 eggs to genetics and environment does not mean that genetics account for 6000 kg of milk or 110 eggs and environment accounts for 9000 kg of milk and 90 eggs. Rather, components ascribe differences among phenotypes of animals to genetic and environment. On an average, 2 eggs of a 10-egg difference between hens might be considered genetic and 8 eggs might be due to environment.

For genetic evaluation, identifying systematic sources of environmental differences among animals is desirable. Once identified, options for standardizing the residual environmental component of phenotypes include changes in management, use of correction factors, and statistical adjustment. An example of a management change is distributing related animals across different pens or pastures. Standard adjustment factors apply to weaning weights of calves born to younger mothers producing adjust weights upward to mature cow equivalents. A contemporary group consists of animals treated similarly. A common contemporary grouping is herd-year-season consisting of animals born in the same herd, year, and season. Statistical analyses for genetic evaluations typically adjust contemporary groups simultaneously.

Heritability

Heritability describes how much of the differences in phenotypes among animals treated similarly is due to genetics. It is the most basic connection from phenotype to DNA and genetic evaluation. Heritability is the ratio of genetic variance (VG) to phenotypic variance (VP) and ranges from 0 to 1. High heritability values of 0.5 mean that on average half of the differences among phenotypes of animals are genetic. Low values of approximately 0.1 mean that most of the differences are not genetic. Multiplying heritability times the differences between each animal's phenotype and their average is a simple genetic evaluation. The accuracy of these genetic evaluations is the square root of heritability.

Several types of genetic variance exist. Additive genetic variance predicts permanent and continued response to selection. Other types of genetic variance (dominance and epistatic) do not predict long-term, continuing selection responses. Broad sense heritability describes the ratio of total genetic variance to phenotypic variance as discussed above. Narrow sense heritability describes the ratio of additive genetic variance to phenotypic variance. Genetic evaluation calculations use estimates of additive genetic variances.

Using the average of several measurements of a phenotype can substantially increase heritability. The variance of the average of N independent measurements is 1/N times the variance of one measurement. A phenotype like wool weight is measured each year of a ewe's life. The variance of an average phenotype (VPAV) is the sum of the genetic (VG) and permanent environment (VPE) variances, which are repeated each year, and the residual variance (VE) that is independent from one measurement to the next is divided by N: VPAV = VG + VPE + VE/N. The heritability of an average is VG/VPAV. Table 1 shows how VG and VPE affect heritability of the average phenotype. New technologies may make it easier to measure traits repeatedly leading to higher accuracy genetic evaluations.

Pedigrees

Pedigrees describe genetic connections among animals. Pedigrees record the male (sire) and female (dam) parents of each

Table 1 The relative increases in heritability of an average of repeated measurements from adding an additional measurement is more when genetic variance (G) is lower, variance from permanent environment (PE) is lower, residual variance (E) is greater, and there are few measurements

Variances			*Number of measurements*			
G	*PE*	*E*	*1*	*2*	*4*	*8*
10	15	75	0.10	0.016	0.23	0.29
10	5	85	0.10	0.17	0.28	0.39
30	15	55	0.30	0.41	0.51	0.58
30	5	65	0.30	0.44	0.59	0.70

animal. Relationships like full-sibs (same sire and dam), half-sibs (same sire or same dam), grandparents (grandsire and granddam), and irregular relationships become apparent from accumulating and linking sire and dam relationships. Many breed associations have a long history of recording sires and dams of purebred livestock and creating pedigrees. Individual breeders and companies also maintain private pedigrees for their use internally. Figure 1 shows pedigree diagrams emphasizing ancestors or families.

Related animals share a portion of their DNA. Pairs of close relatives (sire and a daughter; two full-sibs) share more DNA than distant relatives (two animals with the same great grandsire). The phenotype of any animal that shares DNA with a genetically evaluated animal can contribute to that evaluation. The degree of contribution depends on how much DNA they share and the number and relationships to other animals with phenotypes. The coefficient of relationship (R) between two animals in a noninbred population is the average amount of shared DNA between them. Values of R for simple relationships are 0.5 for parent and progeny or full-sibs; 0.25 for half-sibs; and 0.062 5 for animals sharing a single grandparent. Calculation of R usually considers only the paired chromosomes and not the sex chromosomes but it is possible to consider them separately.

Actual livestock populations have many complex relationships among animals. Calculating R in these populations depends on tabular methods and other algorithms that can extend to very large populations and breeds. The result of these calculations is a relationship matrix, an array of values showing an R value for every pair of animals. Table 2 shows a small portion of a relationship matrix in a cattle herd with R values from 0.016 to 0.520 for five animals. Genetic evaluations now use relationships among millions of animals by combining efficient algorithms with rapidly increasing computational capacity.

An animal receives half of its DNA from each parent. Each parents' half in an animal is also a sample of half of the parents' DNA. This limits the accuracy of predicting a progeny only from its parents' phenotypes or genetic evaluations. Sampling parents' DNA means their progeny will still be genetically variable but genetic variability of full-sibs will be half that of unrelated animals. This remaining genetic variation, called Mendelian sampling variation, limits the accuracy of genetic prediction using only parental information to a maximum correlation of 0.71.

There are two ways that phenotypes from relatives can help in genetic evaluation. When potential sires and dams have phenotypes, then relatives with phenotypes can increase the accuracy of evaluation. When potential sires or dams do not have phenotypes, using related animals with phenotypes is necessary. Sex-limited phenotypes like milk or egg production

	2	0	0.22	0.33	0.41	0.46
	2	0.2	0.20	0.31	0.38	0.43
	4	0	0.29	0.43	0.50	0.55
	4	0.2	0.24	0.36	0.43	0.48

are examples of phenotypes not measured in males. It is common to base genetic evaluation for dairy and egg production on the phenotypes of sires' daughters. Selection of animals harvested and measured for carcass and meat quality phenotypes is not possible. Some early pig improvement programs harvested a few pigs from each litter to get genetic evaluations for carcass phenotypes on the remaining full-sib littermates. Sometimes being reared in the same litter makes mammalian full-sibs more similar than expected from genetics alone. These litter effects make information from full-sibs less independent than full-sibs raised separately. Because they are less independent, litter effects reduce the value of phenotypes from full-sibs for genetic evaluation.

Table 3 shows how accuracy of an animal's phenotype compares to accuracy of progeny or full-sib averages. Use of many daughters can yield accurate genetic evaluations for sex limited or other phenotypes but it increases the time needed and cost of genetic evaluation. Full-sib phenotypes also yield lower but adequate accuracy, usually without increasing time delays. Opportunities to make use of full-sibs in mammals are limited. When possible, direct measurement of an animal's phenotype is usually the best information for genetic evaluation and selection programs. Technology affects the balance of time and accuracy in the breeder's equation. Reproductive technologies can produce clones, an even closer relative, for harvest phenotypes and sexed semen for more efficient production of daughters. Measurement technologies such as ultrasound can measure harvest-related phenotypes in live animals.

Genetic Correlation

Phenotypic correlation is the term that describes animals with high values for one phenotype also tending to have high (or low) values for another phenotype. Correlations are positive when high values occur together and negative when high values in one trait occur with low values in another. Desirable describes positive correlations of phenotypes selected in the same direction and negative correlations of phenotypes selected in opposite directions. Antagonistic describes positive correlations of phenotypes selected in opposite directions and negative correlations of phenotypes selected in the same direction.

Partitioning phenotypic correlations into genetic and residual components is similar to partitioning variation in phenotype. The genetic correlation describes how the genetic values for two traits associate. A biochemical pathway common to two traits and affected by genetics is one of the causes of genetic correlation. Part–whole associations (birth weight and weaning weight) also create genetic correlations. Another basis is close linkage of DNA differences that affect different pathways. Direct genetic and residual environmental components of phenotypic correlation are often either both positive or both negative but it is possible to have a positive and a negative component.

Livestock breeders use genetic correlations to improve accuracy, reduce time needed for evaluation, and expand the scope of genetic evaluation. Carcass lean meat yield is difficult to obtain. Measurements on harvested progeny can delay accurate genetic evaluation and reduce intensity of selection. Ultrasound and other live animal measurements on correlated phenotypes like fat thickness and muscle area remove some constraints of successful and timely genetic evaluation of lean meat yield.

Litter sizes of sows and carcass fat thicknesses of harvested pigs are examples of phenotypes not measured on the same animal and have no basis for a phenotypic correlation. If the sows and pigs are related, there is a basis for estimating a genetic correlation. Genetic correlations between reproductive and productive phenotypes are important for evaluating any opposing effects from selecting either type of phenotype. Some male reproductive phenotypes predict female reproductive phenotypes in females. Genetic correlations help determine the amount of change possible using phenotypes in one sex to predict those in another.

One use of genetic correlation is to measure correspondence between progeny raised in different environments and management systems measured for the same phenotype. Other uses are substitution of an inexpensive measurement for a correlated expensive phenotype; predicting later life phenotypes from early life ones; and using a phenotype that can be measured several times to improve accuracy of a correlated genetic evaluation.

Statistical and Computational Advances in Genetic Prediction

A goal of genetic evaluation is the prediction of differences in average phenotypes of future progeny, known as breeding values. Knowing the accuracy of these predictions is also important. A basic piece of information used in prediction calculations is the difference in an animal's phenotype from the average of the group of animals it came from. Some groups of animals raised similarly are large and the averages are accurate. In many cases, groups of animals treated similarly are small and poorly estimated. C.R. Henderson at Cornell University developed a statistical technique called Best Linear Unbiased Prediction (BLUP) that overcame many problems of genetic prediction including the simultaneous estimation of group means and other adjustment factors along with breeding

values. BLUP methods are now widely used by livestock industries to predict breeding values.

Steady advances in the adaptation of BLUP techniques to different situations encountered in livestock breeding made this technique increasingly valuable. Advances in computational power, application of numerical analysis methods, and efficient memory storage algorithms also contributed toward its broad adoption. Initial applications of BLUP were restricted to predicting breeding values among sires for a single trait but this expanded to sires and maternal grandsires and then to individual animals (Animal Model BLUP) for direct and maternal breeding values. Additional enhancements included simultaneous prediction of multiple traits and prediction of categorical traits like survival.

Using Molecular Genetics and Genomics in Selection

Polymorphisms

Livestock breeders made important and large genetic changes in animals without knowing or being able to know the specific changes occurring in DNA. Tremendous advances in mapping differences in DNA, called polymorphisms, and sequencing DNA of livestock began in the 1990s. Complete DNA sequences (genomes) of several livestock species are now available (USDA National Animal Genome Research Program website).

Scientific and commercial groups searched genomes for polymorphisms associated with phenotypes beginning with the earliest DNA sequencing and mapping of genetic markers. Genetic markers are biochemical tests that identify particular polymorphisms. A genotype consists of the two polymorphisms found at the same location on a pair of chromosomes and each polymorphism is called an allele. Researchers often underestimated the number of animals needed to identify repeatable associations of phenotype with genetic markers. However, they identified many useful genetic markers associated with phenotypes, especially phenotypes with large or distinct effects like specific malformations.

Association of a polymorphism with a phenotype occurs because it directly causes a difference or because of linkage with another causal polymorphism. Linkage results from two polymorphisms being in proximity on the same chromosome. Linkage causes two polymorphisms to be in the same animal more often than expected if they were independent. A shared ancestor creates linkage in progeny (**Figure 2**) that fades in following generations. A population's historical development can create long-term linkage, usually among very close polymorphisms, called linkage disequilibrium.

Associated effects of alleles and genotypes are categorized as additive, dominant (or recessive), and epistatic. Allele G effects are purely additive if average phenotypes of animals with heterozygous CG genotypes are halfway between average phenotypes of animals with homozygous CC and GG genotypes. If the average phenotype for animals with CG genotypes is closer to GG than CC genotypes, then G is a dominant allele. If phenotypes of CG animals are closer to those with CC genotypes, then G is a recessive allele. The CG genotype of a completely dominant G allele is equal to GG and that of a completely recessive G allele is equal to CC. Overdominance describes a heterozygous genotype with a phenotype beyond the range of either homozygous phenotype. Epistasis is the dependence of additive and dominance effects of an allele on genotypes somewhere else in the genome. **Figure 3** illustrates different allele effects and an example of epistasis.

Many identified genetic diseases in animals are recessive (Ibeagha-Awemu *et al.*, 2008; Online Mendelian Inheritance in Animals website). Bovine leukocyte adhesion deficiency (BLAD) is one such disease resulting in high susceptibility to bacterial infection of cattle. A widely used dairy bull heterozygous for the susceptibility allele produced many sons and daughters in the 1950s and 1960s. Eliminating recessive disease alleles is difficult because animals heterozygous for the disease producing allele have the same phenotype as animals without the allele. Molecular genetics and genomics technology can identify specific DNA variations that cause these diseases. Once identified, developing genetic tests for the disease causing alleles is straightforward. Breeders apply these tests to dozens of livestock genetic diseases. Selection reduces

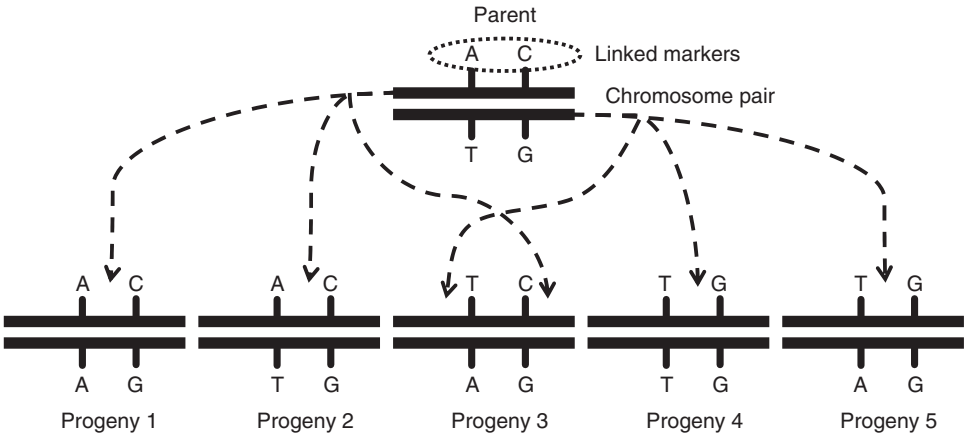

Figure 2 Linked genetic markers on a section of paired chromosomes are often inherited together. Dashed lines show parental chromosome source in progeny chromosomes. Progeny 3 shows mixed chromosomal sources resulting from a crossover in replicating the parental chromosome.

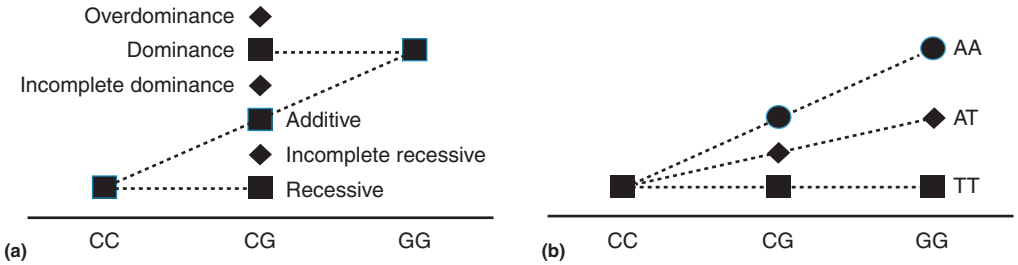

Figure 3 Description of (a) allele G effect depends on average phenotypes of heterozygous (CG) and homozygous (CC an GG) genotypes, and (b) an example of epistasis involving two polymorphisms in different locations.

frequencies of alleles causing many diseases in livestock populations.

Two examples in cattle illustrate differences in controlling genetic diseases with and without DNA tests. Snorter dwarfism is a mutation that was common in US Hereford and Angus cattle during the 1940s and 1950s. Elimination of this mutation took over a decade. The main approach was to eliminate possible carriers having an ancestor who had produced a dwarf calf. Arthrogryposis multiplex, known as curly calf syndrome, became a problem in American Angus cattle in 2007–2008. By the end of 2008, molecular geneticists developed a DNA test for the mutation. Within a year 90 000 cattle were tested to identify 18 000 carriers. A published list of tested carriers enables Angus breeders to manage the defect by avoiding matings of carriers and untested progeny of carriers without eliminating otherwise desirable carrier animals from their herds. The advent of DNA testing for genetic defects has shifted control of defects from disruptive eradication by eliminating all known carriers and their suspect progeny to management of the mutations by testing and not mating known or potential carrier animals. Elimination of the mutation is gradual and mutation-free progeny from otherwise desirable carrier animals retained with DNA testing.

Different causal polymorphisms may result in similar phenotypes. Myostatin is an example of a gene that has several different polymorphisms that cause increased muscling and decreased fat in cattle, pigs, sheep, and other species as well. Multiple causal polymorphisms create genetic ambiguity. Different populations and breeds will tend to have different polymorphisms that result in similar phenotypes. A genetic marker test based on a causal polymorphism will only predict the phenotype in some populations and may only predict some of the animals within a population.

Linkage disequilibrium arises in populations as they fluctuate in numbers of parents and immigrants throughout their genetic history. Any two populations can have both shared and independent parts of their genetic histories. Linkage disequilibrium that arises during their shared genetic history may persist for many generations and be the same in both populations. Linkage disequilibrium arising during their independent genetic histories will not be consistent in the populations. When the basis for a genetic marker test is linkage disequilibrium with a causal polymorphism, then the test is more likely to be valid in populations that share greater and more recent genetic histories.

One of the approaches to identify the strength of linkage disequilibrium is haplotyping. Polymorphisms in strong disequilibrium form inherited groups of alleles. Three polymorphisms with two alleles for each could form eight combinations (AGT, AGC, ACT, TGT, ACC, TGC, TCT, and TCC) but strong disequilibrium may result in only three or four actually occurring (e.g., AGT, AGC, TGT, and TCC). When similar haplotypes occur in different populations, then causal polymorphisms linked to the haplotype should also be similar.

Genetic marker tests derived in one population may not work in another because causal polymorphisms and linkages with the causal polymorphisms can differ in populations because the causal polymorphism in one population might be absent in another population. The National Beef Cattle Evaluation Consortium (NBCEC website) and the SmartGene for Beef project (SmartGene website) conducted validation tests of some genetic markers used in beef cattle and available from commercial companies.

Many traits emphasized in commercially available genetic marker tests are costly, difficult, or available too late in life to evaluate accurately using phenotypes and pedigrees. These include meat quality, disease resistance, fertility, and efficiency. Selection based on genetic markers has the most potential for these traits. However, the same constraints also affect the success of discovering associations of genetic markers with these traits.

Genomic Selection

Beyond simply inherited mutations and traits affected by a single gene or small set of interacting genes with large effects are a myriad of complex diseases and traits influenced by genetics and environmental conditions. Recent genomic technologies enabled development of panels with dozens to hundreds of thousands of genetic markers for livestock species. Genotyping costs for these panels are very economical and open the door to different approaches for using genomic information. Other improvements in DNA sequencers have made sequencing of many individual animals affordable. Targeted sequencing of the 2% of the genome that codes for proteins (exome) is another approach being used to access DNA information across the whole genome. DNA sequence information reveals some of the structure and types of genetic polymorphisms as well as their genotypes across the genome.

Sequencing genomes and exomes and genotyping hundreds of thousands of individual animals are much more affordable now than just a few years ago; however, it is still not

cost effective. A strategy proposed and adopted in some selection schemes is the prediction of missing genotypes through a process called imputation. This process begins by identifying key animals for DNA sequencing or genotyping with panels of tens or hundreds of thousands of genetic markers. Identifying key animals usually begins with sires of males considered for selection, one of the four selection pathways, and then sires of females considered for selection. Other animals descended from key animals are genotyped with smaller panels of hundreds to several thousand genetic markers. Imputing genotypes uses both linkage disequilibrium among the genetic markers and pedigree to fill in all genotypes for animals genotyped only with smaller panels.

Although genetic evaluation using performance and pedigree records has been effective for some traits, including marker genotypes in genetic evaluations can increase accuracy or allow earlier evaluations. If genetic markers accounted for sufficient genetic variation in a trait, then the accuracy of newborn animals could be similar to that of a parent having several progeny measured for the trait. The terms genomic selection and genome-wide selection describe selection based on panels of many markers spread widely across the genome. There are several approaches to implementing genomic selection, and supporting research is rapidly progressing.

One approach to genomic selection begins by genotyping a large training population using imputation with a large panel of genetic markers or from sequencing individual animals. Phenotypes measured in the training population are then associated with genotyped and imputed polymorphisms. One way of applying results from the training population to the population under selection is imputing the same set of genetic markers in the selection population by genotyping a combination of larger and smaller panels of genetic markers. Alternatively, a smaller panel of genetic markers selected from the most highly associated set of genetic markers in the training population is genotyped in the selection population.

Geneticists use both small panels consisting of markers selected based on association with a suite of production traits and large, whole-genome panels having enough markers to ensure unknown causal polymorphisms in the genome will be associated with genotyped genetic markers to explain genetic variation. Low-density panels can reduce costs of genotyping either by direct use of their genetic markers or as a tool to impute large panel genotypes in conjunction with large panel, reference genotypes of influential ancestors.

Another source of training information that works well in dairy and beef cattle is the progeny averages of widely used sires. These sires have hundreds to thousands of progeny measured for some traits. Progeny averages approach half of true genetic differences and eliminate much of the dam and nongenetic variation. If there are enough widely used sires, then genotyping only these sires can lead to good estimates of genetic marker effects. However, this method is limited to traits measured in many progeny. Other important traits that are difficult to measure need other types of training populations.

One of the difficulties of estimating genetic marker effects is that there are often many more genetic markers than training animals. This leads to spurious associations with the markers and erroneous genomic predictions in other populations. Research on statistical methods and other approaches is addressing this problem. Two approaches to limit or prioritize genetic markers for use in genomic prediction include using markers in or near genes that are part of relevant metabolic pathways and using genetic markers with predicted severe effects on proteins.

After genotyping and measuring phenotypes in the training population, a new animal's predicted genomic value for a trait in the selection population is the sum of marker genotypes multiplied by estimated effects of each marker for that trait. Livestock breeders would use these genomic predictions for selection when no other information is available on a trait. Sometimes animals or their relatives will have both genomic, phenotypic, and pedigree information for a trait. One approach to combine this information is an index weighting the genomic values and the genetic evaluations based on phenotypes and pedigree. A second approach uses a standard two-trait and pedigree genetic evaluation treating the genomic breeding values as genetically correlated traits. A desirable byproduct of this approach is an estimate of the proportion of genetic variation explained by the genomic predictions. High proportions indicate that genomic predictions are working well and are appropriate for the population.

Single-step methods simultaneously estimate genetic marker effects and combine either or both genotypes and phenotypes of animals to produce genotype-assisted genetic evaluations. This method uses genomic relationships to replace pedigree relationships when animals have genotypes. Pedigree relationships are expectations of proportions of shared genome based on parentage but genomic relationships measure similarity of genotypes to estimate sharing.

These approaches effectively increase accuracy of young genotyped animals for routinely recorded traits within well-studied breeds and breeding populations, extending the predictions across breeds remains a challenge. Although marker effects estimated in a specific population can account for much genetic variation within that population, applying those effects to genotypes from an unrelated population seldom explains enough variation in the unrelated population to have a meaningful impact on breeding value accuracy. Meeting the challenge of robust genomic predictions applicable across livestock populations could enable meaningful genomic predictions for traits that are economically important but too difficult and expensive to measure routinely.

Breeding: Plants, Modern

JB Holland, North Carolina State University, Raleigh, NC, USA

Published by Elsevier Inc.

Glossary

Epistasis The dependence of one gene's effects on the state of a different gene in the same organism.
Genomic selection The use of a large number of genetic markers across the genome to predict breeding values of plants that have not been grown and tested yet.
Germplasm The material representing the genetic diversity available to a breeding program, often stored as seeds or vegetative plant cuttings or maintained in living nurseries.
Linkage disequilibrium Alleles at different genes that cooccur in individuals more often or less often than expected by chance are in linkage disequilibrium; more precisely this is termed 'gametic phase disequilibrium' because it does not require physical linkage on a common chromosome.
Marker-assisted selection Selection for deoxyribonucleic acid markers previously identified as linked to or inside of desired alleles at genes controlling important traits.
Quantitative trait loci (QTL) A chromosomal region associated with variation for a quantitative trait.

Historical Development of Plant Breeding Methods

The Diversity of Mating Systems in Plants

Mating systems in plants are highly diverse, much more-so than in vertebrate animals. Some plant species have exclusively or primarily outcrossing ('allogamous') mating behavior enforced or promoted by sex chromosomes (like domesticated animals), self-incompatibility mechanisms, or spatial/temporal separation of male and female flower development. Typically, these species have morphological and developmental features that represent adaptations to insect and wind-borne pollen dispersal. Primarily outcrossing species tend to have population structures similar to many animal species, characterized by higher levels of genetic diversity within populations, higher levels of heterozygosity within individuals, and more genetic load (recessive alleles that reduce fitness when homozygous). Many perennial tree and forage species have outcrossing mating systems and population structures (Richards, 1997), as do most fruit crops (Janik, 2006). Many annual vegetable crops and some cereals such as maize are also predominantly outcrossing (Allard, 1960).

In contrast, many other important crop species are primarily self-fertilized ('autogamous') annual species. Many self-fertilized species have morphological/developmental features that promote self-pollination (such as maintaining closed flowers until after pollen shed) and often lack the 'showy' floral features of insect/animal pollinated species. Self-fertilized species tend to have significantly lower levels of genetic variation within populations, lower heterozygosity within individuals, and generally suffer little inbreeding depression, presumably because much of their genetic load was purged during the evolution of the self-fertilization mating system. Most of the cereal grass crops (such as wheat and rice) and annual seed legume crops (such as soybean, common bean, pea, and peanut), and a number of other important crops (including tomato, tobacco, cotton, lettuce, and pepper) are predominantly self-pollinated (Allard, 1960).

Still another group of plants reproduces using both asexual and sexual means (to varying proportions). Important crops in this category include potato, sweet potato, sugarcane, and many perennial grasses (Ortiz *et al.*, 2006; Wu *et al.*, 2006). Many ornamental cultivars are sterile interspecific hybrids and are necessarily propagated asexually. Asexual propagation can occur naturally by spreading stem structures, such as rhizomes, or by asexually produced seed ('agamospermy' or 'apomixis'). Apomixis occurs when viable seeds are formed in the absence of sexual reproduction (Richards, 1997). Beyond naturally occurring mechanisms for asexual reproduction, humans have devised methods to propagate vegetative plant parts (by stem or tuber cuttings, grafting, or even tissue culture). Grafting has deep roots (so to speak) in agriculture and was known to the ancients (Janik, 2006). Citrus is an interesting example that demonstrates the reproductive flexibility that even a single plant group can possess. Citrus trees are naturally self-pollinated but also can be outcrossed easily, usually forming seeds from sexual reproduction. Some types of Citrus, however, will also produce seeds asexually, which represent clonal copies of the maternal plant. Some forms of Citrus will produce both sexual and asexual embryos within the same seed (Richards, 1997). Beyond this natural variability in the reproductive mode of citrus, plant breeders have devised methods of asexual propagation from clonal propagation of a genotype by grafting vegetative cuttings to artificially producing novel hybrids by cell fusions (Gmitter *et al.*, 2009).

These mating system and cultivar type divisions do not follow phylogenetic relationships; all types may (and often do) occur within a taxonomic family (Richards, 1997). For example, the grass family, *Poacea*, contains cross-fertilized, self-fertilized, and asexually reproducing groups (Richards, 1997). Furthermore, most perennial grass species can be propagated vegetatively, and some grasses also reproduce apomictically. For plant breeders, the reproductive behavior of a species is almost always the critical determinant of the breeding method that will be most commonly employed for crop improvement (Allard, 1960). Thus, breeders of soybean (a member of the

eudicot family) and spring-sown wheat (monocot family) will use much more similar breeding methods than will wheat and maize (both monocots) breeders. Perhaps more dramatically, breeding methods used for some forest tree species (mostly outcrossed, and with substantial attention paid to measurements of individual plants and their known pedigree relationships with other trees) are fundamentally more like animal breeding methods than wheat breeding methods.

Furthermore, in the same way that plant reproductive systems largely determine the genetic structure of natural populations, the reproductive system also is the most important factor in determining the predominant genetic structure of cultivars. The mating system has two major impacts on cultivar type. First, the mating system has a critical effect on the relationship between heterozygosity and vigor in the species (Allard, 1960; Richards, 1997). Primarily outcrossing species rely on heterozygosity (having two distinct copies of a gene) to shield the plant from the effects of deleterious recessive mutations. Thus, most outcrossing species exhibit strikingly reduced vigor and fitness when inbred (inbreeding depression) and greater vigor when crossed to unrelated plants of the same species (hybrid vigor). In contrast, self-fertilizing species have adapted to a genetic constitution characterized by high homozygosity, with unfavorable and lethal mutations consistently exposed phenotypically. Self-fertilization appears to have evolved from cross-fertilization in many plant lineages when the detrimental effects of inbreeding were outweighed by the advantages of not having to rely on a separate plant for pollen, as could be important in colonization of geographically isolated habitats, for example (Stebbins, 1974). The second major impact of mating system on cultivar types is its effect on the economic efficiency of cultivar propagation and dissemination. For example, even predominantly self-fertilized species may exhibit some hybrid vigor, so F1 cultivars could be an optimal genetic structure in terms of vigor. Yet, these species also tend to have floral structures and pollination behavior that maximizes self-fertilization and makes cross-fertilization difficult. For example, whereas naturally outcrossing maize has separate male and female flowers facilitating easy emasculation for hybrid seed production, manual emasculation of self-fertilizing species is very time-consuming and requires significant experience to perform well without damaging the female organs. In some species, this has been overcome to some extent by genetic or chemical male-sterility systems, but even then, these species tend to shed relatively little pollen, so that manual pollination and a larger proportion of male to female parent plants may be required to produce seed, increasing seed production costs (Li and Yuan, 2010; Wilson, 1984).

In summary, plant breeding methods and cultivar types can be roughly characterized according to the predominant reproductive system of the species. The result of this is that the genetic structure of cultivars can be categorized according to the level of heterozygosity (within-plant genetic diversity) and heterogeneity (among-plant genetic diversity; **Figure 1**). **Figure 1** is an oversimplification, but captures the large pattern of genetic population structure in different cultivar types. Many older landrace varieties (maintained on farm by farmers over long periods of time) contain substantial genetic diversity. In the case of outcrossing species, this diversity is a natural result of the genetic recombination that occurs with each generation of seed production. In the case of self-fertilizing species, diversity is a result of a mixture of seeds from distinct pure lines resulting from recurrent inbreeding spiked by occasional outcrossing to generate new variability (Allard, 1999). Much of the drive of modern plant breeding has been toward uniformity within cultivars, achieved by isolating pure-breeding lines in the self-fertilized species, or by creating uniform but highly heterozygous F1 cultivars in some cross-pollinated species. As mentioned already, some predominantly inbreeding species are

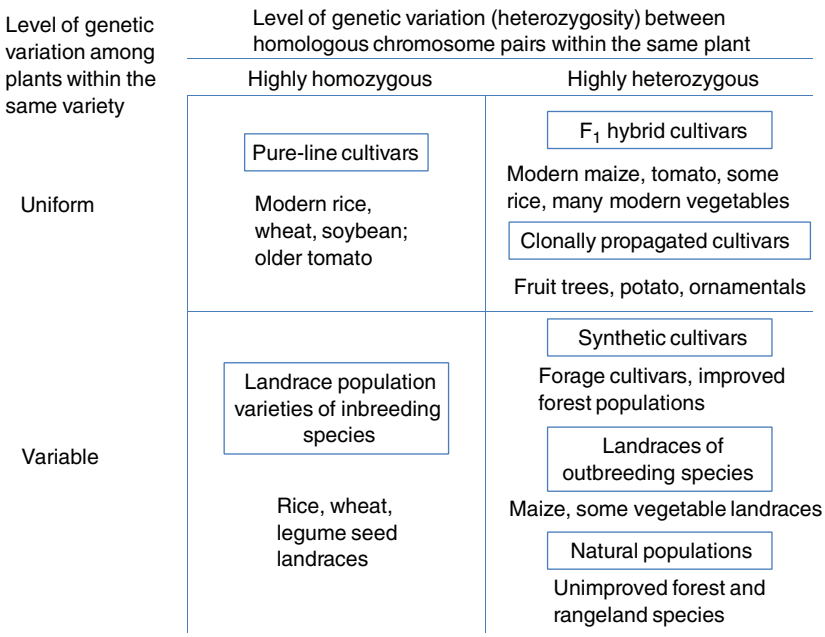

Figure 1 Classification of cultivar types according to genetic diversity among plants within a cultivar and heterozygosity within a plant.

represented by modern F1 cultivars despite the difficulties in seed production, as a way to capture hybrid vigor (which may be limited) and, perhaps more importantly, to more easily combine favorable attributes of different parental lines (e.g., by combining disease resistance with specific fruit quality characteristics).

As with breeding methods, the cultivar types are largely determined by the mating system not the taxonomic grouping of the species, which is why **Figure 1** does not follow a phylogenetic pattern. The predominant genetic structure in most cereal grass cultivars like wheat is a highly homozygous and highly homogenous pure-line variety, whereas maize (an outcrossing cereal grass) cultivars are most often highly heterozygous F1 hybrids.

The Concept of Heritability

Ancient plant domesticators and breeders achieved tremendous gains from selection with no understanding of the biological mechanisms underlying inheritance. Key to this success, however, was the understanding that offspring tend to look more like their parents than unrelated individuals. Thus, it was surely intuitive for ancient plant breeders to use seeds from more desirable plants to sow the next generation. Much less intuitive was Darwin's insight that natural selection, if repeated over many generations, could result in the appearance of new species (Darwin, 1859). Darwin developed his theory of the origin of species by natural selection with an entirely incorrect understanding of the mechanisms of inheritance (Darwin, 1859). Nevertheless, he understood correctly that most traits related to fitness are to some extent heritable from parent to offspring. Thus, absent an understanding of genetics, the concept of inheritance alone is sufficient for effective selection and for basic understanding of the evolution of species.

The synthesis of Darwinian concepts of evolution by natural selection with Mendel's genetics greatly enriched our understanding of both evolution and genetics. The recent developments in genome biology have similarly had profound impacts on these areas of science. Modern plant breeding is a naturally integrative applied field of science, whereby breeders leverage the understanding of inheritance, trait expression, and population dynamics to design more efficient and more effective means of crop improvement. Similarly, plant breeders apply tools and technologies (from genomics, computer science, statistics, agricultural engineering, and so forth) to the extent that their application will help make selection responses better for a fixed input of time and resources. Thus, whereas a simple understanding of inheritance enabled dramatic changes in crops over thousands of years, modern breeders hope that better understanding of the specific details of the inheritance of important traits and the application of tools that permit more accurate discrimination among the potential utility of different plants will greatly speed up the rate of gain from selection. Indeed, recent history suggests that plant breeders have achieved more dramatic gains in the last 100 years in some crops than occurred previously over much longer time scales. The changes in yield potential, stress tolerance, and population genetic structure of maize represent a good example of this phenomenon (Duvick *et al.*, 2004; van Heerwaarden *et al.*, 2012).

A major step toward modern plant breeding was achieved by Johannsen, who studied the inheritance of bean size and weight (Allard, 1960; Johannsen, 1903, 1911), demonstrating that bean populations were a mixture of distinct pure lines, and that selection among those lines would result in heritable changes. Importantly, he noted that while there was also variation among plants within a pure line, selection within lines had no effect on the progeny mean values. He realized this was because there are two components of observable 'phenotypic' variation: (1) 'genotypic' variation because of differences in genetic composition, and (2) variation because of environmental factors. Within a pure line, there is almost no genotypic variation; thus the observed variation is almost entirely because of different reactions of a common genotype to varying environmental conditions. Differences between pure lines are because of both genotypic differences and also environmental differences, so some proportion of those differences will contribute to a response to selection in the progeny. This distinction between genetic and nongenetic causes of variation was critical to providing a sound scientific basis for selection. It made clear that different population structures had different levels of genetic variation, and that selection would have more effect in population structures with more genetic variation. Additionally, by distinguishing the important contribution of environmental effects to observable phenotypes, Johannsen's insights led breeders to consider more carefully how to reduce the contribution of environmental differences among plants under selection, so that selections were determined more by genotype variation rather than nonheritable environmental variation.

Following critical early experiments demonstrating that continuously varying traits could arise as the result of the combined action of multiple genes and the environment (East, 1910, 1916), Fisher (1918) formulated a statistical genetic model that partitioned the overall effect of genotypes into the 'additive' (average) effects of their component genes, dominance interactions between the two copies (alleles) of the same gene in an individual, and epistatic interaction between alleles at different genes. This model led to a formulation of the genotypic variance in a population as the sum of the variation because of additive, dominance, and epistatic effects of component genes.

The importance of conceptually distinguishing the different components of heritable genotypic variation was emphasized by Lush (1945), who coined the term 'heritability' to refer to the proportion of total phenotypic variation observed for some trait in a population that is heritable. Using the terms of Fisher's model, Lush demonstrated that only the additive genetic variance contributes to the heritable genetic variance (Lush, 1940). The reason for this is that in diploid outcrossing organisms, each parent contributes one of the two alleles at each gene in an offspring. Thus, the dominance interaction between the two alleles carried by a parent at a locus is not transmitted to its progeny; dominance effects contribute to variation among individuals, but not to the similarity of parent and offspring. So, if the total genotypic variance (σ^2_G) of a population is composed of additive (σ^2_A) and dominance (σ^2_D) variation (and for simplicity ignoring epistatic effects)

($\sigma^2_G = \sigma^2_A + \sigma^2_D$), then the total phenotypic variance is composed of these components plus environmental variance:

$$\sigma^2_P = \sigma^2_G + \sigma^2_\varepsilon = \sigma^2_A + \sigma^2_D + \sigma^2_\varepsilon$$

The proportion of that total phenotypic variance that is heritable is the heritability (h^2):

$$h^2 = \frac{\sigma^2_A}{\sigma^2_P} = \frac{\sigma^2_A}{\sigma^2_A + \sigma^2_D + \sigma^2_\varepsilon}$$

Lush (1940) referred to this as the narrow definition of heritability; now commonly referred to as 'heritability in the narrow sense' (Falconer and Mackay, 1996) to distinguish it from a broader definition of heritability ('heritability in the broad sense'):

$$h^2_{BS} = \frac{\sigma^2_G}{\sigma^2_P} = \frac{\sigma^2_A + \sigma^2_D}{\sigma^2_A + \sigma^2_D + \sigma^2_\varepsilon}$$

(Falconer and Mackay, 1996).

These two measures have clear and distinct interpretations. Heritability in the broad sense is the proportion of total phenotypic variation that is because of genotypic differences, and refers to the distinction made by Johannsen between genotypic and phenotypic variation. Heritability in the narrow sense has a very important meaning to breeders because it indicates how effective selection will be; in outcrossing populations, the response to selection (R) can be predicted as $R = Sh^2$, where S is the selection differential (the difference between the average of the selected individuals and the whole population). The response to selection refers to the difference between the progeny phenotype values derived from selected parents compared to what the population mean would be expected to be if selection had not occurred (and all parents or a random sample of parents had contributed equally to the next generation).

Lush's definition of narrow-sense heritability is considered the gold standard in quantitative genetics because of its direct relationship with response to selection (Falconer and Mackay, 1996). Note, however, that Lush (an animal breeder) conceived of selection acting on values of individual diploid animals with no possibility of self-fertilization. This is precisely the situation considered by animal breeders and human quantitative geneticists, such that deviations from this definition are considered undesirable and an abuse of the term heritability. Unfortunately, for plant breeders, the reproductive diversity of plants discussed previously immediately causes problems with the definition of heritability (Nyquist, 1991). In addition, polysomic polyploidy of some important crops (e.g., potato, alfalfa, strawberry, many forage, and turf grasses), also creates havoc with the definition of heritability. Finally, the unit of measurement in many plant breeding programs is the total or average production value of a line or family grown in dense populations, such that the measurement of individual values is difficult or meaningless; the result is that the appropriate estimator of heritability in these situations is not the true narrow-sense heritability, but a measure of the heritability of family mean or total values (Falconer and Mackay, 1996; Nyquist, 1991).

Extending Heritability to Polyploidy and Complex Mating Systems of Plants

To demonstrate the more complicated nature of heritability in plants that can arise even in the case of regular outcrossing similar to the animal breeding situation, consider first a relatively simple case of a tetrasomic tetraploid like potato. Each plant carries four homologous copies of each chromosome type (instead of two copies as in diploids). This means that the genotypic value of a potato plant is the sum of the effects of four alleles at the locus, plus all their possible interactions. Each pair of alleles can have a dominance interaction similar to the case in dipoids, however there is also the possibility of higher-order interactions among the alleles at a single locus – the three- and four-way interactions of the alleles. It would be a helpful simplification to ignore the higher-order interactions; unfortunately, substantial evidence indicates that higher-order allelic interactions have a strong effect on yield and vigor in autotetraploids like potato (Mendoza and Haynes, 1974) and alfalfa (Groose *et al.*, 1989). Even if one could ignore all higher-order allelic interactions in a crop like potato, consider that in regular sexual reproduction, each tetraploid parent contributes two alleles per locus to each offspring. Thus a dominance effect because of the interaction of two alleles can be transmitted from parent to offspring, implying that some proportion of the dominance genetic variation should be admitted as part of the definition of heritability in this system (Holland, 2001; Levings and Dudley, 1963).

The situation becomes more complicated when we introduce the more complex reproductive systems of plants (Nyquist, 1991). Consider further the potato breeding situation outlined above. A potato plant can be intermated sexually to generate outbred progeny, which can be subjected to selection based on phenotype, similar in concept to an animal breeding scheme. The utility of a selected cattle sire in a dairy breeding program, however, is in its ability to be mated to dams to generate daughters that can be used in dairy production. Thus, its breeding value really is determined by its additive genetic effects, because all of its daughters carry only one of its alleles. In contrast, if a potato breeder identifies a particularly superior plant, that plant can be vegetatively propagated by tuber cuttings, and those tuber pieces can be used in production by farmers. Thus, the response to selection in this case involves the whole genotype of the plant that is clonally propagated, including all of its additive and dominance effects. So, the response to this selection is a function of the broad-sense heritability, not the narrow-sense heritability in this case.

At the other extreme, a typical breeding method in self-fertilizing species is to make a cross between two varietal parents, then inbreed the progeny from that mating to nearly complete homozygosity. In a pedigree breeding program, selection may be applied at each generation of this process. Note that the proportion of heterozygosity decreases by half with each generation, so that dominance interactions become progressively less important and more of the additive variation becomes partitioned among inbred lineages than within, until one reaches the situation of genotypic variation partitioned entirely among (and not within) pure lines encountered by Johannsen. Modeling the contribution of additive variation to

the genotypic variation among and within lines at each generation is simply a function of the level of inbreeding. However, modeling the nonadditive components of inheritance that contribute to variation among and within lines under intermediate generations is quite complicated (Cockerham, 1983) and measuring those components is exceedingly difficult (Edwards and Lamkey, 2002). In such a case, the appropriate measure of heritability depends on which generations are considered the 'selection units' and which are considered the 'response units.' In the simplest case, a sample of completely homozygous inbred lines from a cross can be evaluated, and only the best lines selected. If those best lines are then propagated as cultivars and considered the end product of that breeding cycle, then the heritability in this situation is a function of total genotypic variance among completely homozygous lines (which includes twice as much additive variance as in the outbred population, no dominance variance, but possibly other higher-order genetic components of variance). Thus, it is entirely appropriate in this situation to use an estimator of heritability that does not match Lush's narrow-sense heritability. In situations where the selected lines are themselves intermated to form a new breeding population, which itself may be inbred, the appropriate heritability estimator depends on the generation of the selected lines as well as the generation of the progeny lines. For this reason, plant breeders would do well to label clearly their estimates of heritability in terms of the 'units of selection' and the 'units of response' to which they apply (Holland *et al.*, 2003).

Enhancing Gain from Selection

For a given trait heritability, there is the possibility of enhancing gain from selection by increasing the selection differential (S in the equation above). This can be accomplished by either selecting fewer, more extreme individuals from the population or by growing a larger population sample for a fixed number of selected individuals. However, there is a tradeoff between having to increase resources to evaluate larger population samples versus the detrimental effects of inbreeding and reduced long-term gains from selection that can occur when the number of selected individuals is too small. Most mature plant breeding programs have more or less a fixed amount of evaluation resources and also some target number of selected individuals at each stage, such that the proportion of selected individuals cannot be widely varied without difficulty. An exception to this are some well-capitalized commercial breeding programs for some major crops, such as commercial maize breeding programs, which have increased substantially in scale in recent years (Crosbie *et al.*, 2006) as a means to increase annual gains from selection in a very competitive seed sales market.

Because dramatic changes in the selection differential are often so costly as to be unfeasible, plant breeders have focused intensely on increasing the heritability of important traits as an alternative means to enhance gain from selection. It follows from the definition of heritability that the greater the proportion of additive genetic variance to total phenotypic variance, the greater the expected response from selection. The additive genetic variance is an inherent function of a particular population and generation of inbreeding. Therefore, the breeder has two general ways to increase the heritability of a trait. One is to concentrate breeding on populations that have more genetic variance. The other is to reduce as much as possible the nongenetic contributions to phenotypic variance.

Populations with more genetic variance generally have greater response to selection, so an obvious strategy is to create populations with greater genetic variance. There are two impediments to this. First is the difficulty in identifying those breeding crosses that produce populations with greater genetic variance before they are evaluated, as methods to predict progeny variance based on parental trait or genetic differences have limited reliability (Hung *et al.*, 2012b). Second, breeders usually face a trade-off between the genetic variance of a population and its mean value, because in elite breeding materials, most variation is in the direction of reduced performance. Criteria for selecting among populations include the usefulness statistic that incorporates both the population mean and its variance (Melchinger, 1987; Schnell, 1983) and the mean value of the best families in a population at some consistent percentile (Goodman, 1965), but, again reliable values for these statistics are available only after the populations have been evaluated. When the local elite breeding pool is lacking in sufficient favorable variation, crosses between local and exotic sources of germplasm (perhaps including wild relatives) may be necessary to incorporate the desired genes into a breeding program. Recurrent backcrossing to local materials or longer term planning may be required for such strategies to be successful.

Reduction of environmental contributions to the phenotypic variance is one avenue for improving gain from selection that breeders can often implement without major difficulty. For the purposes of this discussion, it is well to distinguish variation because of macroenvironmental differences (such as the average performance difference of a population among different locations or over years) from variation because of microenvironmental variation that occurs within a particular year and location combination. Further, when breeding populations are evaluated across macroenvironments, the possibility of genotype-by-environment interaction (differences in relative performance of varieties across environments) must be considered (**Figure 2**). A common breeding strategy is to evaluate a set of families across multiple environments and to select based on their average performance. Each family is tested at all environments such that all family means are averaged over all macroenvironment effects, eliminating the macroenvironment effects from the phenotypic variance of family means. (Even if some data are missing from some environments, one can still estimate mean values that take into account the macroenvironment effects so that genotype comparison are not influenced by the macroenvironment effects.) The heritability of family mean differences across environments is

$$h^2 = \frac{\sigma^2_G}{\sigma^2_G + \frac{\sigma^2_{GE}}{e} + \frac{\sigma^2_\varepsilon}{re}}$$

where the genetic variance among families, σ^2_G, is some function of the additive variance that depends on the type of families

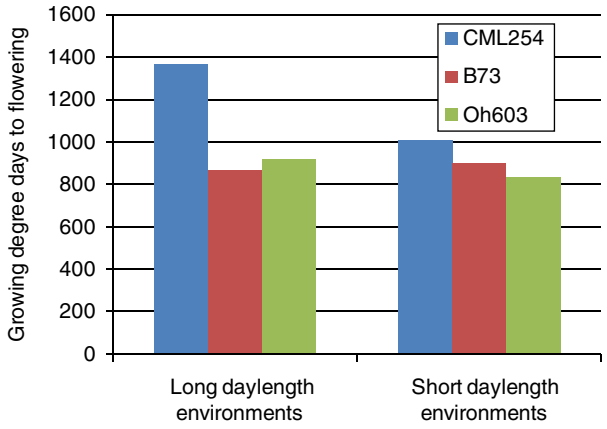

Figure 2 Example of genotype-by-environment interaction: thermal time to flowering of three maize inbred lines grown in long or short daylength environments. Relative ranking of time to flowering for the three lines changes between these two groups of environments. In this particular case, genetic differences in photoperiod sensitivity among lines determines their reactions to different daylengths.

and their inbreeding level, σ^2_{GE} is the genotype-by-environment interaction variance, σ^2_ε is the average within-environment microenvironmental variance, e is the number of environments used for evaluation, and r is the number of replications per family per environment. This equation shows that the heritability, and consequently, the expected gain from selection, can be often increased by increasing the number of testing environments e. If the breeder includes environments that are too distinct, however, the genotype-by-environment variance component may increase and overwhelm the genetic variance component, causing heritability to decrease. In such situations, it pays to identify more homogenous subsets of environments and split the breeding program to select for families that are superior within regions, rather than to continue to search for families that are superior across the whole range of macroenvironments (Ceccarelli, 1989; Simmonds, 1991).

Another component of the heritability equation that the breeder can exercise some control over is the within-environment microenvironmental variation (also known as the experimental error variation). As seen in the equation above, the contribution of this component to the denominator of heritability can be reduced by increasing either the number of testing environments or the number of replications at each environment. There is a nearly direct trade-off in resources between increasing the number of replications evaluated and the number of unique genotypes that can be tested. Fortunately, breeders can avail themselves of experimental designs and statistical analysis methods that can help reduce the experimental error variance without requiring additional testing resources. The major challenge to controlling experimental error in breeding trials is the large number of genotypes to be evaluated. With many genotypes to evaluate, the total physical field size required to plant all of them often become so large that the microenvironments of plots can become quite different across the testing field. Most commonly, soil quality may vary across the field so much that comparing the yield of a variety grown on one side of the field to a variety grown on the other side measures more the difference in soil quality than genetic yield potential. Good crop management is critical to minimize such effects, but experimental designs that break the whole field required for a single complete replication of the entries into subblocks can also help significantly. Lattice, alpha, augmented, *p*-rep, and row-column designs are particularly useful (Cullis *et al.*, 2006; Patterson and Williams, 1976; Williams *et al.*, 2011; Wolfinger *et al.*, 1997). In addition to improved experimental design, newer methods that attempt to model the spatial effects on experimental errors can contribute significantly to improving response to selection (Brownie *et al.*, 1993; Gilmour *et al.*, 1997; Qiao *et al.*, 2004; Smith *et al.*, 2005).

Beyond changing the selection differential and heritability, the breeder has an additional avenue through which the response to selection can be improved: reducing the time required to conduct a cycle of selection. Annual crops can be evaluated for only one generation per year in their target production environment. Breeders may be able to use greenhouses or offseason nurseries (in tropical/subtropical locations or in the opposite North/South hemisphere where seasons are offset) to obtain additional generations per year. Unfortunately, greenhouses and offseason nurseries are not useful for evaluating yield potential in the target production environments. Selection aimed at some traits with simple genetic control (such as major gene disease resistances) may be effective, but for the most part, greenhouses and offseason nurseries are most useful for advancing breeding generations (such as selfing, backcrossing, or making new hybrid combinations for breeding or testing) without selection. This alone is useful, but does not directly increase the number of selection cycles per year. Speeding up backcrossing, however, may enable breeders to more quickly introduce new disease resistance genes or transgenes into elite genetic backgrounds, particularly if they are able to easily select for the presence of the desired gene using deoxyribonucleic acid (DNA) tests or simple phenotypes. Lewis and Kernodle (2009) demonstrated an elegant method to dramatically reduce time to flowering in tobacco by transformation with a flowering time promoter, and using these rapid flowering types as targets for backcrossing a desired gene from an undesired genetic background. After the final generation of backcrossing, the breeder can select against the flowering time transgene and for the target gene to recover the desired gene in the genetic background of the elite parent with its normal flowering phenotype. Breeders have searched for other ways to use these additional generations grown outside of their target production environments, and later in this article, a recent approach using DNA marker information alone to conduct selection in these environments will be discussed.

Another way to reduce the time required to conduct a cycle of selection is the use of doubled haploids in species where inbred lines are created as part of the breeding program (Forster and Thomas, 2005). Doubled haploids require special techniques such as anther/pollen culture, wide crossing, embryo rescue, and inducer stocks. The effort required to obtain sufficient numbers of doubled haploid progeny in some cases has limited the utility of doubled haploids. In maize, however, doubled haploid breeding has gone from a rarely used approach to a widespread method in commercial maize

improvement programs in the past decade. This resulted from the development of genetic stocks that combine a relatively high frequency of haploid induction as a pollinator with a simple color marker that permits rapid visual discrimination among diploid, haploid, and outcross progeny to make the recovery of haploids from new breeding crosses relatively simple and efficient (Rober *et al.*, 2005). Proprietary methods to efficiently double the chromosome numbers of large numbers of haploid plants have probably also made an important contribution to this breeding method.

New Statistical Techniques for Selection

Statistics have long been an important tool for plant breeding; improvements in experimental design have increased the efficiency of selection, as noted in the Section Enhancing Gain from Selection. When experiments are well designed and executed, relatively simple statistical analyses can often remove much of the influence of extraneous macro- and micro-environmental effects from the mean values of the genotypes. To handle nonrandom spatial field effects, however, more complex models may be needed. Such models relaxed the assumptions of standard ordinary least squares analysis of variance, such as the assumption that error effects are uniformly and independently distributed among test plots. Instead, one could test a model that, for example, models the error effects on some pair of plots as having a correlation that is greatest for adjacent plots and decreases in magnitude as the plots considered are more distant physically. To perform such an analysis, however, requires a shift from standard analysis of variance techniques to mixed linear models. The mixed linear models analysis is more computationally intensive and requires specialized software; the necessary computation power and software were not widely available to plant breeders until approximately 20 years ago.

The mixed linear models approach has broadened considerably the range of models that can be tested for plant breeding experiments. One example is the modeling of spatially correlated residual error effects, as just mentioned. More complex models can also be applied to multiple environment trial data sets, such as allowing each environment to have a unique amount of experimental error variance, which is a more realistic model than the constraint of a common error variance assumed by the traditional analysis of variance. An important change in the concept of genotype-by-environment interaction variance has been fostered by the ability to flexibly model different forms of such interactions using mixed models. One example that seems particularly appealing is a model that allows each environment to express a different amount of genotypic variation and allows each pair of environments to have a unique correlation between genotypic values. This allows the breeder to identify easily which pairs of environments produce similar phenotypic responses from a common set of genotypes, and which pairs of environments produce unrelated, or perhaps even negatively correlated phenotypic responses. This helps breeders to select optimal sets of testing environments that will capture as much of the range of environments in the target production region, and can help determine if the breeding program should be partitioned to select for different subsets of genotypes adapted to specific environmental subsets.

Fitting more complex mixed models is not simply an academic exercise in better capturing the nongenetic effects on experiments, however. The mixed model has a different philosophical underpinning for effects that are considered random (meaning that they are samples randomly drawn from some larger population of effects) versus fixed (meaning that the effects studied are the ones of direct interest, and they are not assumed to be drawn from some larger reference population). The practical effect of treating genotypes as random in the mixed model is that their genetic value is predicted with a best linear unbiased predictor (BLUP) instead of estimated with a best linear unbiased estimator (BLUE), such as a mean value (Robinson, 1991). BLUPs and BLUEs may rank genotypes differently, because BLUPs incorporate a shrinkage factor that makes them closer to the overall population mean than their respective BLUEs. The amount of shrinkage depends on the trait heritability (higher heritability traits have less shrinkage) and the amount of information available for a particular genotype. For example, if a genotype has missing data from most environments in a multienvironment trial, but has an outlier phenotype based on a small amount of available data, its BLUP will be shrunk back toward the mean more strongly than genotypes with more data. This is a sort of penalty on those genotypes that have more missing data, and would lead to them being less likely to be selected on the basis of BLUPs, even if their mean BLUE value would have ranked them very highly. The mixed model analysis accounts for the differences among environments in terms of different error variances, amount of genetic variance, correlation with other environments, and so forth, such that the effect of missing data on shrinkage depends on the environment from which the data is missing. Importantly for practical breeding purposes, BLUPs have higher accuracy than mean values, so selection on BLUPs is expected to result in better response to selection (Piepho *et al.*, 2008).

Best Linear Unbiased Predictions Incorporating Pedigree Information

Another key improvement that mixed models and BLUPs have begun to deliver to plant breeding programs is their ability to incorporate information on relationships among lines and individual plants in the breeding pool. This methodology was pioneered by Henderson (1974) and widely adopted in animal breeding before plant breeders began to recognize its utility and applicability to problems in plant breeding (Bernardo, 1996; Panter and Allen, 1995). Plant breeders long recognized that closely related lines have similar phenotypic responses, but Henderson's BLUP methodology allowed precise incorporation of quantitative estimates of genetic similarity based on the amount of shared pedigree between each pair of lines or individuals into the predictions of genetic value (Lynch and Walsh, 1998). The importance of this method is to leverage observed phenotypic information on each line to improve the predictions of other lines to which they are related (Piepho *et al.*, 2008). Extending this idea further, Bernardo (1996) showed that plant breeders could improve

the efficiency of their programs by initially testing a diverse subset of lines, then predict the genetic value of all of those lines, plus the value of untested lines using the known pedigree relationships among the tested and untested lines and the BLUP method. The lines with highest predicted values (whether directly tested or not) could then be identified for further evaluation, thus concentrating testing resources on lines with the best chances of being superior. This concept has evolved more recently into genomic selection (see Section Using Genetic Markers In Selection Programs), where the concept of breeding value prediction has been further refined through the application of genetic marker information.

New Sources of Germplasm

A basic premise of plant breeding is that response to selection occurs by the increase of favorable allele frequencies, and concurrent decrease of unfavorable allele frequencies in breeding gene pools. In the long run, plant breeding that is effective should reduce genetic variability in breeding populations. This poses a problem for breeders: progress from selection depends on genetic variation in breeding populations, but such progress tends to ultimately reduce such variation.

Most crops suffered substantial genetic bottlenecks during the domestication process (Tanksley and McCouch, 1997). Domestication tends to impose strong selection for the domestication type: for grain crops, for example, the nonshattering trait greatly simplifies harvest and was strongly selected for across many species (Harlan, 1992). Domestication also imposed significant selection for traits such as loss of seed dormancy and seed size in seed crops, reduction of thorns and awns, and flavor and fruit size in fruit crops (Allard, 1999). In allopolyploid crops such as wheat and oat, multiple bottlenecks occurred: the interspecific hybridizations and subsequent chromosome doubling occurred naturally, but these are very rare events which involve very small population sizes, and were then followed by the typical population bottleneck during domestication (Sears, 1969). This explains the quite low level of genetic variation in wheat compared to other crops (Cox and Wood, 1999). Acting against this domestication bottleneck were subsequent gene flow between sympatric wild and domesticated species (van Heerwaarden *et al.*, 2011) and human selection for very diverse phenotypes (such as the dramatically different plant forms of cabbage noted by Darwin (1859) and for adaptation to widely divergent environments (Allard, 1999; Ruiz *et al.*, 2008; Wallace and Brown, 1988). Mutation, genetic recombination, mating system, and population sizes were also important factors in shaping the diverse levels of genetic variation among crops.

Seed banks and germplasm repositories represent an important genetic resource holding alleles that have been eliminated from modern elite breeding pools but that may have some value to modern agriculture (Tanksley and McCouch, 1997). Major challenges of using gene bank materials are a lack of relevant information on characteristics that may be of use to a particular breeding program and the linkage of favorable alleles to many generally unfavorable alleles at nearby genes in the unadapted genetic backgrounds of most germplasm resources. Harlan and de Wet (1971) proposed a classification of cultivated plants from the point of view of their practical utility to plant breeding programs. In their system, taxa are organized into primary, secondary, and tertiary gene pools. The primary gene pool consists of all taxa that are fully interfertile with the cultivated species; the secondary gene pool includes taxa that can be crossed to the cultivated species but produce hybrids with low fertility or poor chromosome pairing; the tertiary gene pool includes those taxa whose hybrids with the cultivated species are lethal or completely sterile, such that specialized techniques such as embryo rescue and chromosome doubling are required to obtain any fertility in the progeny (Harlan and de Wet, 1971). This classification emphasizes that most breeding crosses should be restricted to the primary gene pool to have the greatest chance of success of recovering an improved cultivar. Nevertheless, even within the primary gene pool of most crops, there are huge differences in adaptation, productivity, acceptability for commercial production, and genetic load. Thus, breeders usually will attempt to incorporate diversity from already improved materials that are distinct from their elite gene pool, but lack significant problems of adaptation or acceptability. Where such materials do not carry the desired favorable alleles, breeders must access less adapted germplasm and expect to need additional generations to break up unfavorable gene linkages and may need to use backcrossing techniques to reduce the overall contribution of the donor of diversity. Despite these difficulties, there is ample evidence that 'exotic' sources of germplasm within the primary gene pool can be effectively used to improve elite gene pools even for highly polygenic traits such as yield (Goodman, 2004; Simmonds, 1993; Tanksley and McCouch, 1997).

For species such as wheat, which suffered severe bottlenecks during their evolution, the primary gene pool may not carry the genetic variation needed for specific traits. Substantial effort in transferring disease and pest resistances from the secondary and tertiary gene pools has been made in wheat, resulting in the development of numerous specialized techniques to recover progeny from wide crosses, induce recombination, and recover stable cultivated types carrying desired target genes (Friebe *et al.*, 1996; Jiang *et al.*, 1993). These approaches, particularly the use of the tertiary gene pool, require longer-term commitment to successfully proceed from initial crosses to an agronomically acceptable cultivar expressing the trait of interest.

In general, the use of secondary and tertiary gene pools is restricted to the introgression of one or a few genes from a particular donor parent. The objective of introgression programs is to recover a variety that carries the target genes from the donor parent but as little genetic material from that donor as possible. This is usually achieved through repeated backcrossing to the recurrent elite cultivated parent, but if the chromosomal structure of the donor is too different from the cultivated parent, the chromosome segments around the target gene may not pair well and recombination may be suppressed. Without adequate recombination, even many generations of backcrossing may result in the maintenance of large chromosomal segments carrying many genes, which, other than the target gene, are likely to be undesirable (Young and Tanksley, 1989).

Introgression programs aimed at introducing genes from the secondary and tertiary gene pool are more likely to be

successful in polyploid species. Successful examples of this work abound for diverse polyploids such as wheat, potato, and sugarcane (Jansky and Peloquin, 2006; Jiang *et al.*, 1993; Simmonds, 1993), but are unheard of in, for example, diploid maize (despite some effort) (Harlan and de Wet, 1977). This is a result of the greater capacity of polyploid genomes to 'buffer' against the deleterious effects of large chromosomal introductions and unbalances that occur during such breeding schemes.

The use of transgenic technologies (gene transformation) can also be considered as part of the toolkit for introducing genes from the tertiary gene pool. Genetic transformation has expanded the tertiary gene pool (at least for some crops) to include all living species, so, for example, the gene that encodes a protein toxic to lepidopteran insects could be transferred from the bacterium *Bacillus thuringiensis* to crop plants (Koziel *et al.*, 1993; Perlak *et al.*, 1990). Genetic transformation is also sometimes considered the ultimate tool for introgression, as only the desired target gene is introduced into the cultivated crop, conceptually eliminating the accompanying linkage drag of the surrounding chromosomal segments from the donor. Unfortunately, in most crops, transformation is most efficiently conducted with older inferior varieties (because they regenerate better from tissue culture), necessitating backcrossing the transgene from the old variety into the elite.

Using Genetic Markers in Selection Programs

The genomics revolution has provided numerous technologies that facilitate the rapid analysis of sequence variation in crops. Crops such as maize, wheat, rice, and soybean have extensive genomics resources that allow the relatively rapid development of DNA markers that can be used to track inheritance of specific chromosomal positions. Modern sequencing technologies also have contributed to marker development in many other plant species, but the ability to create marker sets that are readily deployable across breeding programs often requires a deeper understanding of genome structure and variation than exists for some species.

The ability to rapidly assay allelic variation at DNA markers can be of considerable utility to plant breeding programs. This technology is of greatest immediate applicability for the selection of desired gene variants that have sizeable effects on an important trait, have been mapped accurately and precisely (with identification of the causal gene and sequence variant most useful), and for which DNA marker assays are cheaper, easier, or faster than phenotypic identification of progenies that carried the desired gene (Collard and Mackill, 2008; Holland, 2004; Tester and Langridge, 2010; Young, 1999). Some examples where this condition is true and for which marker-assisted selection has become routine for at least some breeding programs include:

- Soybean cyst nematode resistance, a difficult trait to accurately phenotype, but for which a few genes have major effects (Cahill and Schmidt, 2004; Young, 1999);
- Disease resistances and submergence tolerance in rice, encompassing a range of difficulty for phenotyping but for which individual genes with large effects have been identified directly or by tight linkage to markers (Collard and Mackill, 2008; Francia *et al.*, 2005; Ismail *et al.*, 2013);
- Numerous disease resistances and simply inherited fruit quality characteristics regularly targeted with markers in commercial tomato breeding programs (Foolad and Panthee, 2012);
- Disease-resistance genes, self-incompatibility, fruit quality in several fruit crops of genus *Prunus* (Dirlewanger *et al.*, 2004);
- Many (>50) simply inherited disease resistance and grain quality characteristics targeted by public wheat breeding programs (Dubcovsky, 2004; Eagles *et al.*, 2001; Gupta *et al.*, 2010; Miedaner and Korzun, 2012).

The experience with marker-assisted selection in wheat breeding is particularly instructive, as this has been done almost entirely in the public sector across several countries. Australia pioneered the practical application of marker-assisted selection on a large-scale by creating centralized genotyping facilities to support the applied breeding programs (Eagles *et al.*, 2001). The USA federal government followed suit by establishing four regional small grains genotyping facilities to conduct marker analysis for both public and private sector breeders and by funding a coordinated multistate project to make genotypic selection widely available to applied breeding programs (Dubcovsky, 2004). By removing the burden of marker development and genotyping from each individual breeding program (which typically do not have sufficient resources to perform marker analyses on substantial proportions of their breeding material), the centralized facilities have enabled the integration of marker-assisted selection into cultivar development in small grains. The USA small grains marker-assisted breeding project assisted in the release of at least 90 cultivars.

The wheat example also highlights the trend seen across the examples of marker-assisted selection in other species: specific markers have been most useful for selection when they identify alleles of relatively large effect. Major disease-resistance genes are the most common example of this: the presence of a particular disease-resistance allele can determine completely if a plant is resistant to a particular race of pathogen. In addition to the targeted gene having a major effect, markers are most useful when they are 'diagnostic' for a phenotypic effect across most breeding crosses that are expected to segregate for the phenotype (Collard and Mackill, 2008; Holland, 2004). Although there are special cases in which linkage relationships between linked markers and causal variants tend to hold in breeding programs, high resolution genetic analysis to identify casual sequence variation that underlies desired phenotypes is usually required to obtain a diagnostic marker (Holland, 2004).

Markers have proven particularly useful to backcross breeding programs, where a panel of markers can be used to select simultaneously for the desired allele from the donor parent, against linked donor alleles (to reduce linkage drag), and against donor alleles on other chromosomes (to reduce the number of generations required to recover most of the recurrent parent genome) (Chen *et al.*, 2000; Collard and Mackill, 2008; Frisch *et al.*, 1998; Randhawa *et al.*, 2009).

Implementing markers for selection more generally in typical breeding schemes that involve generating many new breeding families from crosses among numerous parental lines can be more difficult, as it requires diagnostic markers to be widely useful and efficient. Some effort is often required to determine (based on pedigrees and previous knowledge of which founder lines carry specific alleles of interest) which sets of markers can be fruitfully applied for selection in specific breeding populations.

Marker selection can be most useful if it can be applied to single plants (or seeds) in early generations before substantial effort on phenotyping has been expended (Collard and Mackill, 2008). Rather than attempting to identify a plant or plants homozygous for all of the desired marker alleles in early generations (which would require astronomical population sizes if the number of target genes exceeds a few), gene enrichment strategies that select for plants carrying at least one desired allele at as many genes as possible can be far more efficient and practical for implementation in applied programs (Bonnett *et al.*, 2005; Wang *et al.*, 2007). The key concept is to use markers to identify a subset of the breeding population that has the greatest chance of carrying desired alleles for a number of simply inherited traits so that more expensive field phenotyping for other complex traits of agronomic importance can be concentrated on lineages that are most likely to result in a cultivar possessing most of the desired characteristics. Thus, markers do not replace phenotypic evaluations, but instead help to focus phenotyping resources on lines that are enriched for favorable alleles affecting a subset of traits.

In contrast to the situation where trait expression is largely controlled by one or a few genes and for which marker-assisted selection can be very efficient, traits with complex genetic control have been less amenable to marker-assisted selection. Returning again to the example of wheat breeding, an important trait for both yield and grain quality is resistance to Fusarium head blight disease. Unlike some other wheat disease resistances that are largely controlled by a small number of genes with large effects, such as leaf rust and stem rust, Fusarium head blight resistance is under more polygenic control. Numerous genes with smaller effects contribute to the inheritance of this trait and environments exert substantial influence on the expression of this disease. Therefore, it has been difficult to accurately identify the genome locations and effects of the underlying genes. Instead, regions of the genome have been identified as containing quantitative trait loci (QTL) for Fusarium head blight resistance, but these regions are generally only loosely defined and may contain hundreds of genes (Buerstmayr *et al.*, 2009). Worse, the QTL identified in any one linkage mapping study often have little correlation to those identified in a different cross (Buerstmayr *et al.*, 2009). Thus, at this time, breeders have reliably diagnostic markers for only one Fusarium head blight resistance QTL, which confers only a portion of the resistance in some crosses, and has no effect in other crosses (Buerstmayr *et al.*, 2009). The situation is similar for many other complex traits in wheat, such as grain yield and abiotic stress resistances (Francia *et al.*, 2005). There is no evidence for, nor reason to believe, that a particular marker can be diagnostic for any highly polygenic trait in any species (Bernardo, 2008; Collard and Mackill, 2008; Holland, 2004). Statistical difficulties limit the ability to precisely refine the position of QTL or to estimate their effects even in one breeding family (Beavis, 1998; Schön *et al.*, 2004), and the underlying biological reality is that different sets of genes segregate in different breeding families, reducing the predictive power of QTL markers for complex trait selection (Holland, 2007).

Simultaneous genetic analysis of multiple breeding families representing the range of genetic diversity of a breeding pool can more precisely identify specific genes controlling complex traits and at the same time provide better understanding of the distribution of allelic effects among important breeding stocks (Holland, 2004, 2007). Association analysis and joint multiple population linkage analysis represent complementary approaches to comprehensive genetic analysis of complex traits.

Association analysis attempts to identify allelic variants associated with trait variation across a diverse sample of breeding materials. If linkage disequilibrium decays rapidly with physical sequence distance in the sample, association analysis can provide precise identification of the genomic position of sequence variation affecting a trait, possibly facilitating the identification of a causal gene and its causal sequence variation (Ersoz *et al.*, 2007; Flint-Garcia *et al.*, 2005). In addition to potentially higher resolution than linkage mapping, association studies have the benefits of being directly applicable to existing breeding pools without requiring development of specialized mapping families and sampling a greater diversity of alleles (Breseghello and Sorrells, 2006; Ersoz *et al.*, 2007; Myles *et al.*, 2009). A number of experimental and statistical challenges impact the feasibility of association analysis, including the choice of environments used to measure phenotypes of diverse germplasm sampled from a wide range of zones of adaptation, the accuracy of phenotypic measurements, the frequency of the causal allele, and the ability to measure genetic variation for the trait after accounting for population structure (Breseghello and Sorrells, 2006; Larsson *et al.*, 2013; Morrell *et al.*, 2012; Myles *et al.*, 2009; Yan *et al.*, 2011; Zhu *et al.*, 2008). If the genetic regulation of a trait is already well understood from knowledge of biochemistry or model systems, a relatively small number of genes may be considered candidate genes to be tested for association with the trait, increasing one's chance of identifying a causal gene (Harjes *et al.*, 2008; Wilson *et al.*, 2004; Yan *et al.*, 2010). For many important traits, however, one has little or no understanding of the genes or biochemical pathways that might be involved in their expression. In such cases, genome-wide association studies can be attempted, whereby a very large number of single nucleotide polymorphisms (SNPs) are tested for association, in the hope that some causal variants are in linkage disequilibrium with at least one SNP each (Huang *et al.*, 2010, 2012; Morris *et al.*, 2013; Olukolu *et al.*, 2013; Wisser *et al.*, 2011). Genome-wide association studies also have the advantage that they test for variation in noncoding regions of the genome, which turn out to be over represented in the set of SNPs associated with trait variation in some cases (Li *et al.*, 2012).

Joint multiple population linkage analysis combines information from several related biparental cross populations to improve power and resolution of QTL identification and also to characterize the distribution of allele effects in different founder lines representing some portion of the diversity of a

breeding pool (Blanc *et al.*, 2006; Coles *et al.*, 2010; Holland, 2007). The largest such studies in maize have revealed substantial complexity for most quantitative traits, characterized by numerous genes of relatively small effects at which the allelic effects are dispersed among founder lines (Brown *et al.*, 2011; Buckler *et al.*, 2009), demonstrating the futility of predicting QTL effects across populations for highly polygenic traits.

Joint multiple population linkage analysis can be integrated with genome-wide association study to combine the advantages of well-defined population structure and accurate and inexpensive imputation of dense sequence variation from parents to mapping progenies from linkage analysis to the higher resolution provided by association analysis (Hung *et al.*, 2012a; Kump *et al.*, 2011; Tian *et al.*, 2011). These approaches have permitted the identification of SNPs and other sequence variants associated with complex traits at high power, but again reveal the substantial complexity of quantitative traits at least in outcrossing maize, because most SNPs are associated with only a very small fraction of the observed trait variation. Thus, even identification of specific sequence variants associated with trait variation and their distribution in the breeding pool is not sufficient to enable cost-effective marker-assisted selection, because many markers need to be assayed and the response to selection at any one marker is expected to be too small to warrant its selection. However, even for complex traits, there is usually a distribution of variant effect sizes, and perhaps a few variants might have effects of sufficient magnitude to warrant their targeting for marker selection (Hung *et al.*, 2012a). In addition, association analysis might still be fruitfully applied to traits that are difficult to phenotype but for which a relatively small number of genes are important (Harjes *et al.*, 2008).

An entirely distinct approach to the use of DNA markers for enhancing selection to polygenic traits referred to as genomic selection has developed rapidly in the past decade as a way to address the shortcomings of QTL-based marker-assisted selection. Once again, the seminal work in this area of quantitative genetics-based breeding was done by animal breeders (Hayes *et al.*, 2009; Meuwissen *et al.*, 2001). Plant breeders realized the potential utility of genomic selection and proposed modified schemes that could be integrated into current maize (Bernardo and Yu, 2007), small grains (Heffner *et al.*, 2009; Lorenz *et al.*, 2011), and forest tree (Grattapaglia and Resende, 2011) breeding schemes.

As mentioned already, QTL effects for polygenic traits are difficult to estimate accurately, and this limits the predictive ability of QTL-statistical models even within a single mapping family (Melchinger *et al.*, 1998; Schön *et al.*, 2004), and thus the potential response to marker-assisted selection of QTL (Moreau *et al.*, 1998). QTL models are created by testing each region of the genome for association with the trait and selecting only those marker-tagged regions that appear to have statistically significant effects on the trait. Although the exclusion of markers that do not have strong statistical significance from the prediction model seems sensible, it turns out to limit the predictive power of the models (Moreau *et al.*, 1998). The basic premise of genomic selection is that all markers should be included in the prediction model (Bernardo and Yu, 2007; Meuwissen *et al.*, 2001; Xu, 2003), even when there are more markers than individuals in the test population! Standard regression techniques cannot be used for such 'overfitted' models, so alternative statistical techniques must be used, such as Bayesian analysis, ridge regression, or mixed models with constrained marker variances (Bernardo and Yu, 2007; Meuwissen *et al.*, 2001; Xu, 2003). The details of these analyses are complex, but the key objective of genomic selection is to predict the breeding value of lines in the study as well as lines with genotype information but no phenotype information using the prediction model (Lorenz *et al.*, 2011). Unlike QTL mapping, the prediction models do not attempt to accurately estimate the effects of each genome region, instead they sacrifice accuracy on individual marker effects by overfitting the markers, but increase the accuracy of breeding value prediction based on the net value of markers. In this way, the optimal amount of information about polygenic effects is extracted from the set of lines with both genotypic and phenotypic information (the training data set), providing better predictions for lines with only genotypic data (Heffner *et al.*, 2009), which could represent untested sib lines or progeny generated from crosses among lines in the training data set. Genomic selection models are not expected to provide accurate estimates of the effects of specific genome regions on traits, however.

Bernardo and Yu's (2007) original proposal for implementing genomic selection was in the context of a commercial maize breeding program, in which genomic recurrent selection could be conducted for several cycles on seeds or seedlings in offseason nurseries. Separate genomic selection models could be created for each biparental cross family, which maximizes the consistency of linkage relationships between markers and causal genes over several cycles of selection. Even when genomic marker predictions of phenotypes are less accurate than direct phenotypic evaluations, genomic selection can produce greater gains per unit of time by enabling additional cycles of selection on individuals seeds or plants in offseason nurseries (Heffner *et al.*, 2011a, 2010; Lorenzana and Bernardo, 2009; Massman *et al.*, 2013).

An alternative use of genomic selection is the development of prediction models encompassing lines derived from many different parental combinations rather than just one cross (Crossa *et al.*, 2010; Heffner *et al.*, 2010; Zhong *et al.*, 2009). Cross-validation and simulation studies suggest that this could work (Crossa *et al.*, 2010; Heffner *et al.*, 2011b; Riedelsheimer *et al.*, 2012), but that there are difficulties with combining information across very diverse germplasm sets (Lorenz *et al.*, 2012; Zhong *et al.*, 2009). Windhausen *et al.* (2012) demonstrated that genomic prediction models created by combining diverse maize breeding pools had good accuracy for prediction of germplasm in those same pools, but the prediction accuracy fell to approximately zero when the models were applied to newly created biparental populations. Simply, the training data set used to create the genomic selection model must have a close genetic relationship to the breeding population to which it is derived. Exactly how close this relationship must be is still a matter of investigation. The availability of such large-scale prediction models is likely most useful for well-resourced commercial breeding programs, where the ability to generate and genotype new progeny lines outstrips the ability to conduct high-quality phenotypic evaluations of yield and other complex traits. In this way, the breeding potential of progeny

lines that have never been planted in a field could be predicted, and lines with superior predicted values could be retrieved from storage for future phenotypic evaluations. This approach emphasizes the expenditure of precious phenotypic testing resources for materials that have the best chance of being cultivars or cultivar parents.

Marker-assisted selection and genomic selection are important components of modern breeding programs in many crops. The balance between the use of resources on DNA markers to select for specific gene alleles, genomic selection to select for the 'polygenic background,' and phenotypic evaluations will likely shift as research indicates the best application of each evaluation method. The optimal balance likely will vary among crops and even among different programs in the same crop, as it will depend on the relative availability and cost of genomics resources compared to field testing.

To the extent that genetic dissections of important traits succeed in identifying causal genes and sequence variants (via association analysis, high resolution linkage mapping, or other means), those alleles can be targeted for selection and for incorporation across distinct germplasm groups. This form of 'direct allele selection' (Sorrells and Wilson, 1997) should be more effective at predicting the value of alleles across diverse germplasm than genomic selection models, which are highly dependent on the genetic context in which they are defined. These different selection methods could be combined by identifying a subset of the most important genes and targeting them for direct allele selection, predicting the breeding value of some portion of the remaining background polygenic variation with a genomic selection model, and relying on extensive phenotypic evaluations of a selected subset of lines to make final decisions on cultivar releases. Note that high-quality phenotypic evaluations underlie all three of these aspects of modern breeding.

Glossary

Beginning farmer Farm operator of a farm on which all operators have 10 years or less experience in operating a farm.

Commodity specialization Total value of production equaling at least 50% from one commodity or related group of commodities determines a farm's commodity specialization, consistent with the North American Industry Classification System. Farms that do not have a commodity or livestock type composed of at least 50% of production are classified as other crops or other livestock operations.

Contracting Many farmers market their production through contracts in lieu of open market sales. These farmers and their buyers agree to arrangements in the contract signed before harvest (or before the completion stage for livestock), specifying the terms under which products are transferred from the farm.

Family farm There is no hard and fast definition of a family farm in the United States, unlike the farm definition. The United States Department of Agriculture's Economic Research Service (USDA ERS) defines a family farm as one in which the majority of the business is owned by the operator and individuals related to the operator by blood, marriage, or adoption, including relatives who do not live in the operator household. The share of US farms classified as family farms has changed little since 1996, ranging from 97.1% to 98.3% of all farms.

Farm Any place from which US$1000 or more of agricultural products are sold, or normally would have been sold, during a year. A point system developed by the USDA's National Agricultural Statistics Service is used to determine when a farm normally would have sold US$1000 of products, in the event they do not do so. This point system assigns dollar values for acres of various crops and head of various livestock species to estimate a normal level of sales. These point farms have fewer than US$1000 in sales but have points worth at least US$1000 and tend to be very small. Approximately one-quarter of farms have no sales in a typical year, and at least another 30% have positive sales of less than US$10 000.

Farm operator household Farm operator households share dwelling units with principal farm operators of family farms. Multiple operators who do not share the same household operate less than 10% of family farms. In this case, the farm operator household population includes the households of the principal farm operator, but not those of the other operator(s).

Farm operator household income Income from the farm business and from other farming activities, along with income from earned and unearned off-farm sources, comprise total farm operator household income.

Large-scale family farm According to the 1998 National Commission on Small Farms, large-scale family farms produce US$250 000 or more in gross farm sales. However, different users may use different threshold levels for their purposes, especially because agricultural price levels have changed since the level was established.

Nonfamily farm Farms where the majority of the farm business assets are not owned by the principal farm operator and his or her relatives.

Small farm According to the 1998 National Commission on Small Farms, small farms have gross farm sales of less than $250 000. However, different users may use different threshold levels for their purposes, especially because agricultural price levels have changed since the level was established.

Introduction

This article provides a brief description of general characteristics and changes in production agriculture over time. Key influences or drivers of change in structure and organization, as well as other significant drivers of change, are discussed. Detailed measures of farm size and structure are presented and discussed, including the evolution over time. Economics of different types and sizes of farms are explored, including the importance of off-farm income. The implications of significant trends and their challenges to the future structure and organization of agriculture conclude the article.

Although this article is US specific in its measures used to reflect how the structure and organization of agriculture/

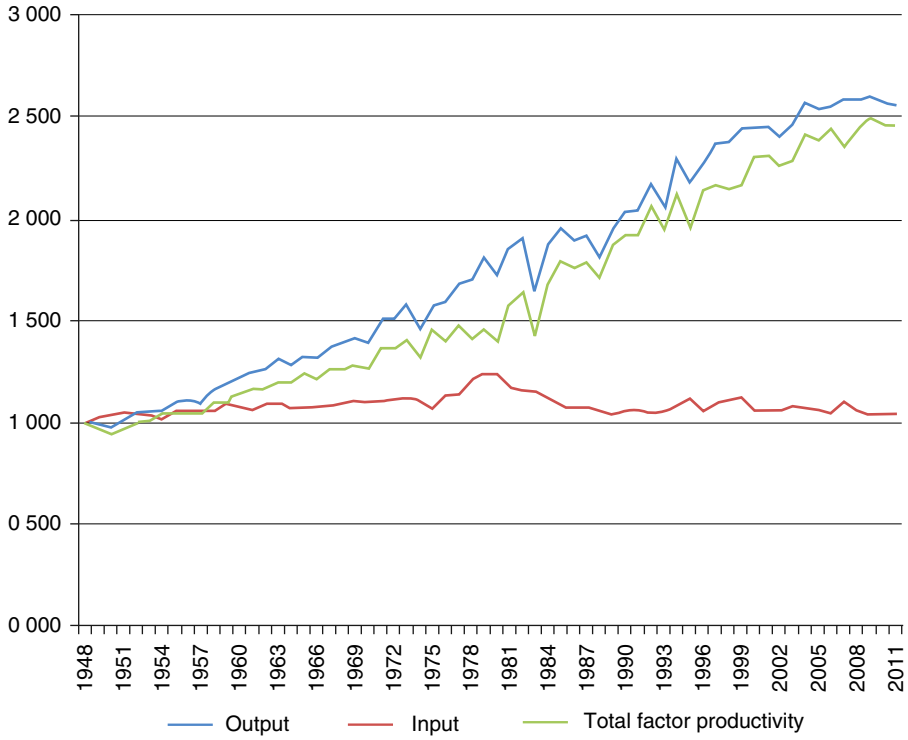

Figure 1 Indices of farm output, input, and total factor productivity, 1948–2011. US Department of Agriculture Economic Research Service, 2013a. Agricultural productivity. Available at: http://www.ers.usda.gov/topics/farm-economy/agricultural-productivity.aspx (accessed 07.07.13).

farming are changing over time, the drivers of change affecting size, structure, and organization of agriculture are largely universal. Quite similar trends are evident throughout most developed countries and are increasingly evident in the emerging commercial farming sectors across Latin America, Africa, and in some other developing countries. The scale and speed of change varies depending on policy, social systems, and cultural preferences, but the key underlying drivers of change are rapidly shared in today's global economy and interconnected world.

Key Drivers of Change in Structure and Organization

Farms in the United States have evolved over time, with more and more production coming from large-scale family farms and a relatively few nonfamily farms. The largest number of farms by far is in the small-size category (under US$250 000 gross farm sales (National Commission on Small Farms, 1998)), with many fewer in the mid-size and large farm-size categories. Small farms produce a relatively small proportion of total agricultural output. This evolution toward a farm sector in which production is concentrated on fewer large farms continues unabated for the most part. Two key drivers of this changing structure and organization of farms are technology adoption and globalization of agricultural markets.

Technology adoption

Increasing size of farms tends to reduce cost of production because of efficiencies in machinery use, cost savings from purchases of larger quantities of inputs at volume discounts, and ability to obtain marketing efficiencies. Larger size farms are often the early adopters of technology derived from research and development, either public or private, leading to increases in productivity. Cost-saving technologies create efficiencies, such as those available from using global positioning systems to guide planting and harvesting machinery and to collect large amounts of site-specific data that facilitate decisions affecting input use, disease-control strategies, and even crop choice. Investments in machinery and accompanying technology have increased significantly, as equipment has become larger and more sophisticated to accommodate increasing scale of operations. The benefit to the producer purchasing such equipment is the efficiency with which planting and harvesting, as well as intermediate field operations, are carried out. The gains partly come from eliminating wasteful overlaps in planting, with accompanying savings in fertilizer and pesticide application costs and in part from the decreased labor time and reduced fuel costs for field operations.

From 1948 to 2011, US agricultural output grew 1.49% per year, whereas the aggregate input use increased only 0.07% annually, so positive growth in the farm sector was mainly due to 1.42% per year productivity growth (Figure 1; USDA ERS, 2013a). Research and development (R&D) leads to technology adoption that often replaces labor and generally reduces costs and increases yields. Technology adoption is fostered by the historic United States Department of Agriculture (USDA)–Land Grant University system wherein basic research findings of the land grant universities established under the Morrill Acts of 1862 and 1890 are transferred to farmers by the state Cooperative Extension programs, which carry out applied research and dissemination

functions, and by private sector firms. The Smith–Lever Act of 1914 authorized these state Cooperative Extension programs in the universities to work in cooperation with the USDA. This collaborative system's success is recognized worldwide, and its structure is often mimicked with varying degrees of success.

Starting in the 1970s, the role of the private sector in carrying out research and development has increased to the point of providing approximately 50% of the combined public and private sector funding for agricultural productivity enhancing research by 2006. This shift was facilitated by expanding intellectual property policy involving animal and plant genetics (Alston *et al.*, 2010). However, the role of the public sector in providing public goods research from which the private sector may not be able to garner profits will continue to be a critical component of technology adoption for agriculture.

Globalization of agriculture

The imports and exports of agricultural and food products tied to globalization put a premium on efficient farm production to hold down costs of exports and to keep lower cost imports from replacing US production. Trade negotiations play an important role in determining the implications of globalization for US domestic agricultural policy and products. Progress in removing or reducing tariffs and import quotas as barriers to trade have facilitated worldwide trade growth in agricultural and food products. Trade negotiations also establish guidelines for the types of food safety or other requirements countries may impose on product quality characteristics. It is critical that standards are not established which are designed primarily to create a barrier to imports from the United States or other countries, which could offset productivity efficiency as a key determinant of trade flows. This is increasingly important amid concerns about food security for the burgeoning world population of poor consumers and a growing middle class demanding improved diets.

Additional Drivers of Change in Structure and Organization

There are numerous other factors that may also drive change in farm size and structure. A number of them are briefly addressed here.

Consumer preferences

Consumer food preferences and expectations are important drivers of change in products sold by retailers. Whether they are also major drivers of change in the size and structure of farms depends on how they influence new opportunities or create challenges for producers. An important preference of consumers is convenience, as more and more households rely on two people in the workforce to provide adequate family income. Food safety is an accompanying concern for consumers who rely on the convenience of food prepared by others, such as packaged produce that has been handled in large-volume processing facilities. Foodborne illnesses, especially occurring in fresh produce and in meats, have received prominent attention in recent years and even partially eroded confidence in safety of the US food system. This led to the passage of the Food Safety Modernization Act (FSMA) in 2011 (Kinsey, 2013). The regulations that implement that Act will have direct implications for costs to producers who will need to increase food safety efforts on the farm. For example, food safety hazard analysis critical control point (HACCP) plans require knowledge about foodborne pathogens and their control. However, as the complexity of products and processes increases, more sophisticated approaches and skills are required to successfully implement an effective HACCP plan. Larger-scale farmers are generally more likely to possess the skills, or to have employees with those skills, to carry out a successful farm-level food safety program based on HACCP plans. This is likely to foster the trend toward larger size farms to spread the cost of such implementation over more units of production. However, farms are exempt from compliance with the FSMA if they sold less than US$25 000 or if they sold less than US$500 000 in the past 3 years and sell at least 51% of product directly to consumers or retail food establishments within their state or a 275-mile radius from their farm. This exemption may offset at least some of the pressure to increase farm size to spread food safety compliance costs over larger acreages.

There is increased interest by relatively smaller segments of the consumer and general population in nonmarket social values – including environmental sustainability, local and regional food systems, humane treatment of food animals, and fair wages for farm workers, to name some of the most prominent. These market segments may increase opportunities for relatively smaller farms to thrive, at least in earlier stages of developing differentiated products for these market niches.

Agricultural policy

There are a number of production-oriented agricultural policies that provide payment to major commodity producers to support incomes. They include such programs as direct payments based on historical yields and acreage, countercyclical payments, loan deficiency payments, disaster assistance programs, or payments tied to conservation practices. Changes in policies over time are surely connected to changes in farming structure (Sumner *et al.*, 2010), although clear causation is difficult to establish. For example, empirical evidence suggests that a share of agricultural program payments are capitalized into the prices of land, but it is difficult to separately identify how that might affect farm structure, apart from the key drivers of structural change (see MacDonald *et al.* (2013) for a review of recent literature).

Other agricultural policy measures may encourage or help to maintain the number of smaller farms. Examples include programs to foster farmers' markets, facilitate purchase of local foods by participants in food assistance programs, and provide federal support for production process verification, which may help smaller producers differentiate their products in the market. However, smaller farms may need to seek out opportunities to collaborate with others to be able to compete successfully in markets, even locally. Individually, they may lack sufficient volume to move much beyond farm stand sales or any local farmers' markets.

Input costs

Input costs, which may be affected by factors outside the control of agriculture, can also be important drivers of changing structure and size of farms. For example, the price of fuel, fertilizer, and debt financing are heavily influenced by factors outside of the agricultural sector. To the extent that their use per unit of farm output varies across farm size, these factors will have an impact on structure. And increases in farm size, perhaps over a number of scattered parcels, may give the farm operator more ability to capture volume discounts for products, transportation, and contracted production services. However, input costs, which they are unable to influence, may put small farmers in a more challenging position in terms of production efficiency.

Risk management

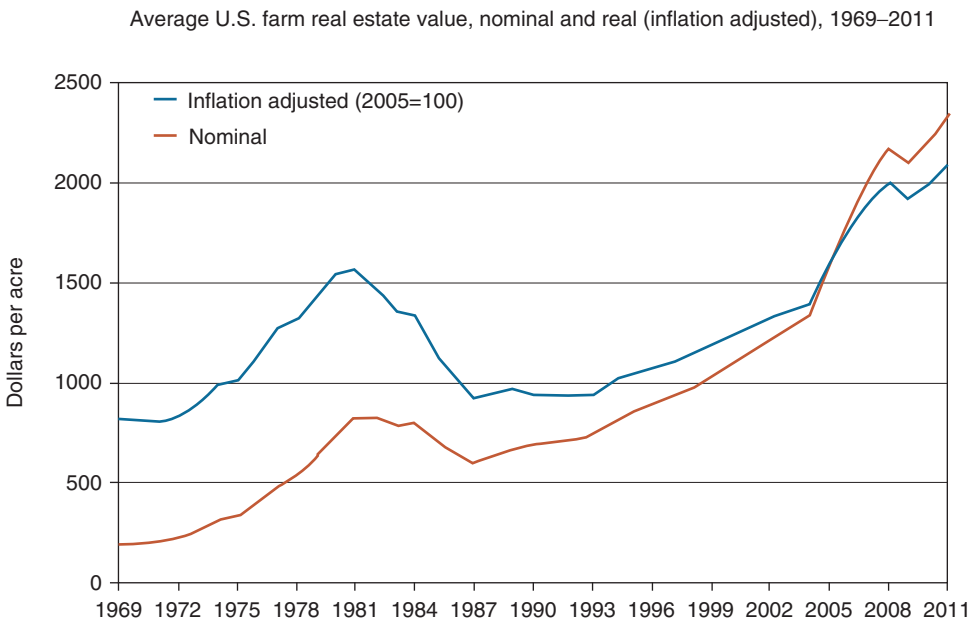
As the size of a farm increases, risk management becomes an evermore challenging element in determining its success or failure. Diversification of production to provide alternative sources of income is one element of risk management that has long been the mainstay of farms from smaller through larger operations. However, with the increasing specialization in a few major commodities in many medium- and large-scale farms in recent years, risk management must be carefully considered in the decision-making processes. Crop insurance subsidized at the federal level, and especially utilized by major field crop producers that tend to be larger than other farms, is one risk management tool that has gained in popularity in recent years. However, research has shown that due to risk-balancing tendencies on the part of a farmer, policies that decrease the variability of farm income could induce farmers to increase their risks elsewhere, such as through increased financial risk (Featherstone *et al.*, 1988). For example, increased financial leverage could provide incentives to increased concentration of production. To what extent insurance will be a mainstay of future farm programs remains to be seen, as policy constantly evolves. Many anticipate increased reliance on insurance programs in the future, in part subsidized at the federal level, as replacing much criticized direct subsidy programs for the major agricultural commodities.

Tax policy

Tax policy involves a variety of provisions that impact how firms and households organize their finances so as to minimize their tax burden and therefore can have indirect impacts on farm structure. For example, tax policy affects the use of capital in agriculture by the provisions associated with expensing of capital acquisition in the calculation of taxable income. The amount of capital costs that can be expensed, rather than placed on a depreciation schedule, are limited, depending on the tax year. For example, in 2000 US$20 000 could be expensed and in 2013 US$500 000 could be expensed. These expensing provisions are especially useful for large and expanding farms. In 2010, 83% of farms with sales of US$500 000 or more made a capital investment, although only 1% of these large farms had capital investments of US $500 000 or more (Durst *et al.*, 2013).

Tax policy may also influence structural change by fostering growth in the number of small farms. Although small farms earn little or nothing in cash income from farming, the key to understand structural change and small farm survivability is to recognize the importance of the full range of returns to farming. Small farm households generally are full owners of their farm land and farm land values have historically, and especially recently, risen rapidly, providing owners with unrealized capital gains (**Figure 2**). However, farm land owners generally receive a reduction in their local property taxes because the land is valued for tax purposes for farm use rather than market value, reducing their cost of investment compared with the cost of owning other real estate.

The majority of farm families reside on their farm property, and therefore many of the expenses associated with the dwelling are included in farm business expenses. According to data from the Internal Revenue Service, since 1980 the aggregate net farm income reported by those that file Schedule F forms (almost 90% of all farms) has been negative. Approximately three-quarters of all Schedule F filers have negative net farm income (Durst *et al.*, 2013). At the same time that farm families may be experiencing rises in the value of their farm land, paying property taxes based on the lower farm use value and having the farm business cover some residential expenses, families with off-farm income benefit from having farm losses that reduce taxes on their nonfarm income. Moreover, many farm residents most likely value the so-called psychic income that comes from a rural lifestyle.



These additional returns to farming were most likely not considered in 1986 when the US Office of Technology Assessment released a report that predicted by the year 2000 there would be 1.2 million farms in the United States. The report stated:

> The projected decline in the number of small farms is dramatic but plausible, given the strong trend in this direction and the persistently negative farm income in this class (U.S. Congress, 1986, p. 96).

The report incorrectly predicted the loss of approximately 500 000 small farms. It also predicted that the 50 000 largest farms in 2000 would produce 75% of all farm products. In fact, in 1997, approximately 180 000 farms produced 75% of the value of all agricultural products. Even in 2007, family farms with greater than US$500 000 gross sales plus nonfamily farms totaled 163 500 (7.5% of total farms) and produced only 71% of total value of production. Adding in the family farms with between US$250 000 and US$500 000 gross sales raises the numbers to 257 000 (12% of total farms) producing 84% of gross farm sales. Although consolidation into large-scale farms has been important in terms of total production, the numbers of farms involved remain quite large compared with earlier projections.

Measures of Farm Size and Structure

Farm size and the relative roles and importance of small family farms, large family farms, and nonfamily farms are integral elements of the structure of agriculture. Family farm income combined from farm and off-farm sources, and the assets owned, compare quite favorably to those of the overall US population.

Figure 2 Average US farm real estate value, nominal and real (inflation adjusted), 1969–2011.

Number, Size, and Commodity Specialization of US Farms

After peaking at 6.8 million farms in 1935, the number of US farms fell until the 1970s. The latest Census of Agriculture for 2007 reported 2.2 million farms (USDA National Agricultural Statistics Service, 2009). The current definition of a farm was adopted in the mid-1970s. It is a very inclusive definition and embraces farms operated by households who are retired or attracted to farming for reasons not primarily related to production, such as the rural lifestyle or investment opportunities. In addition, since the definition is dollar based but not inflation adjusted, it becomes more inclusive with each passing year as price levels change. The number of total farms and the average acreage per farm has been very stable (Table 1).

However, the statistics in Table 1 mask significant structural change over the period. Table 2 shows the number and percent of farms in different constant dollar sales classes for 1982 and 2007. During the period, both the number and the share of farms increased in the very smallest class of point farms (with sales less than US$1000 but normally expected to sell at least that amount of agricultural products) and the two largest classes (with sales of US$500 000 or more). The largest declines were in the mid-sizes of US$10 000–249 999 in sales, which went from 51% of all farms in 1982 to 31% of all farms in 2007. This evidence of a declining middle is a continuation of an ongoing trend.

Cash receipts from commodity production indicate increasing nominal value of products sold, reflecting both quantity increases and price increases (Table 3). Several factors have contributed to this rapid rise in cash receipts from all commodities since the turn of the century. In particular, growth of middle-class consumers in developing countries has created demand for oil crops, food commodity crops, and vegetables and fruits as well as for livestock products and therefore feed crops. The extent to which these price increases will be sustained depends on demand recovery from the recession starting in 2008 in the United States and subsequently experienced in most developed and many developing countries, further demand expansion from rising middle-income countries, continued demand for agricultural products as a source of fuel, and trade policy agreements.

Table 4 shows net cash farm income by commodity specialization and provides financial and other characteristics of the various farm types.

Legal Form of Organization and Farm Ownership

The changing structure of farming to larger sized operations facilitates achieving economies of scale to reduce costs and increase farm income. Some are concerned that the future food supply will be controlled by a small number of corporate farms, leading to higher prices to the consumer. But the reality does not bear out this concern.

A distinctive feature of agriculture is that a large number of family farms control most production, whereas publicly held corporations are few in number and control a minor portion of production. To better understand this issue, it is useful to draw the distinction between family and nonfamily farms and legal organization. The family–nonfamily distinction is based on whether or not an extended family owns most of the assets of the farm business, regardless of legal organization and farm size. In 2011, 97.3% of all farms were classified as family farms, and at least since 1996, the percent of nonfamily farms

US$500 000–999 999	34 650	1.5	60 777	2.8	75.4
US$1 000 000 or more	16 191	0.7	55 509	2.5	242.8

[a]Sales class is based on the market value of agricultural products sold.
[b]Point farms have sales of < US$1000 (current dollars) but are still considered farms because they would be expected to normally sell at least $1000 of agricultural products.
Note: Sales and sales classes are defined in 2007 dollars, using the Producer Price Index for farm products to adjust for price changes. Point farms are identified using current dollars – with no adjustment for price changes – because the minimal level of sales in the farm definition is not adjusted for price changes.

has been between 2% and 3% of all farms (USDA ERS, 2013b). In recent years, nonfamily farms have accounted for between 12% and 15% of the value of agricultural production.

However, legal organization of a farm business is a way to organize ownership and management of the business, largely for tax, liability, and transfer purposes. Legal organization does not require that farms be of a certain size, although large farms are more likely to be organized as corporations than are smaller farms. Legal organization also does not imply a family ownership status. The reality is that many large family farms are

incorporated for sound business purposes. Although the Census of Agriculture asks farms that are organized as a corporation whether or not they consider themselves to be a family corporation, this term does not have a clear definition nor is it a recognized legal form of organization. Census of Agriculture data for 1987, 1997, and 2007 (Table 5) shows that sole proprietors continue to control the lion's share of farm numbers, two-thirds of acres of farmland, and approximately half of total farm sales. Partnerships are next in importance in number of farms and acres and the third most important in farm sales. Although the share of farms organized as partnerships has declined somewhat over the period, the share of their sales has increased. Family corporations control a small portion of farms and gradually growing share of acres as well as sales. Other farms, including nonfamily corporation farms, are a small share of total numbers (under 2%), control approximately 8% of farm acreage, and provide approximately 7% of farm sales.

Table 6 shows the number of farms and amount of farmland operated by the tenure status of farms, i.e., fully own all acres, own part of the acres in the operation, and rent all acres in the operation. More than two-thirds of farms fully own the acreage farmed, but they account for less than 40% of acreage farmed. The share of farms with full ownership increased more from 1997 to 2007 than the share of acres they operated. This is consistent with the increasing share of small farms in the sector over this period, which are more likely than larger farms to be full owners. The share of full tenant farms decreased continuously during 1987–2007. The proportion of land operated by this group of farms has also decreased during that time. Trends indicate that the experience since 1987 is likely to be repeated as structure and size of farms continues to evolve, although the recent historically high rates of increase in the price of farm land may temper the future share of land owned versus leased by large farms.

Finances of Farm Operator Households

The USDA disseminates a wide variety of statistics on farm finances for three general groups of farms. The most closely tracked indicator is the estimate of the aggregated net income of the whole agricultural sector over time. This estimate is the basis for the agricultural portion of the US gross domestic product. The balance sheet of the farm sector is also available at the aggregate level. Although useful to understand the current situation and the outlook of the sector, aggregated statistics provide little structurally relevant information. The USDA also disseminates financial estimates of farm businesses by various structural characteristics, which excludes farms producing relatively small volumes of output and whose operator's major occupation is not farming. Both sets of these farm statistics are available at USDA ERS (2013c). The third farm population for which USDA provides statistics is for family farms, including both farm and off-farm sources of income and wealth. Here the focus is on this latter set of financial statistics because of the important role of off-farm income as a contributor to total family farm income, allowing many farm households to stay engaged in farming and greatly influencing farm sector structure.

Farm Finances

Although small family farms (with gross sales of less than US $250 000) produce a relatively small share (18%) of agriculture's value of production, they controlled 51% of the acreage used in agriculture in 2011 (Table 7) and 64% of farm household assets in 2007 (Hoppe and Banker, 2010). The acreage and assets controlled by the small-scale family farms are down significantly relative to 1990 when they accounted for the vast majority, as reported by Lins (1994). This shift is due to increasing numbers of large-scale family farms and their increased ownership of the acreages farmed compared with the situation in 1990.

On a cash basis, small farms as a group lose money farming. The average small farm cannot generate enough net farm income to support a family farm without outside income sources. Perhaps not too surprising, as farm size increases so too do average farm assets and debt. However, even the smallest farms have large net worth. In 2011, the median net

worth of the 59% of family farms that operated the smallest farms was more than US$440 000, which is more than five times that of the average US family.

Off-Farm Income

A major motivation for the establishment of US agricultural policies in the 1930s was the low incomes of farm families, relative to nonfarm families – the so-called farm problem (Gardner, 1992). Low incomes among farm families are largely a situation of the past, due in no small part to the growth in off-farm income. In 1960, the ratio of farm to US household income was 0.65, compared with 1.25 in 2011. In the past two decades, the rate of increase in the average incomes of farm families has surpassed that of the average US household (Figure 3).

One of the factors contributing to the reversal in the income gap between US and farm households is educational attainment. Formal education is an especially important factor not only in the nonfarm job market but also in today's highly technical farming industry. In the early 1960s, only 4% of principal farm operators had a 4-year college degree, compared with 8% of the general US population. By 2011, the college attainment levels were nearly comparable, 25% for principal operators compared with 28% for the general population (Table 8). Moreover, the US population now has a higher share of the population that has not attained a high school degree, compared with the farmer population (15% compared to 9%). The closing educational attainment gap is even more noteworthy when one considers that the farmer population has a significantly older age structure than the general US population and the educational attainment is higher for younger people in general.

The importance of off-farm income in maintaining the large numbers of farms and acreage along with other assets held by small- and medium-size family farms has been understood for some time (Ahearn, 1986a, b). Without off-farm income sources to sustain family expenses, many of those farmers would likely disappear, greatly reducing the number of farms and likely shifting the ownership of the acreage to larger sized operations. This means that farms located near urban areas or in rural areas with significant industrial or service sector businesses are more likely to have the ability to remain in farming. Beginning farms often rely on off-farm sources of income as they enter agriculture, and the majority of farm families benefit from someone in the household engaged in off-farm work that often provides the family with health insurance.

The shares of income from farm and off-farm sources vary significantly by size of family farm (Table 7). The differences in off-farm income by farm size are consistent with the differences in major occupation of the principal operator. Of the 59% of the smallest family farms, 31% of the operators reported to have a major occupation of farming, compared with more than 90% of the largest 10% of family farms. In 2011, almost 60% of family farms had gross sales of less than US $10 000 and had negative average farm incomes, typically receiving all of their household income from off-farm sources. On an average, they received more than US$77 000 in income from off-farm sources in 2011, which is more than family farm households operating larger farms typically received.

Family farms with gross sales of US$10 000–249 999 represented 30% of family farms in 2011. Although still considered to be small farms, the households operating these farms earned, on an average, positive returns from their operations. They earned less from off-farm sources compared with households operating the very smallest farms, but with their positive farm earnings, they had higher total household incomes than those operating the smallest farms in 2011. Their average (mean) household income was US$79 780 and their median household income was US$60 990, in 2011.

Ten percent of family farms in 2011 had gross sales of US $250 000 or more. Although receiving less in off-farm income than those operating small farms, these larger family farm households earned significantly more on the farms they operated. As a result, they had average household incomes nearly three times the level of smallest farm households. The average household income of farm families operating the larger farms was US$205 000, and the median was US$127 000, in 2011.

Significant Trends

A number of trends or issues facing agriculture are most likely to impact the future structure and organization of the industry. Some are derived from consumer demand for product characteristics and others are a matter of demographics, whereas still others are policy driven.

Sustainable, Organic, and Local Foods

There has been growing consumer interest in sustainably produced food, including organic and more recently local. Sustainable integrates in concept economic profitability, minimum environmental impacts, and social equity and economic opportunity issues. The growth of niche farm categories, such as organic, sustainable, local market oriented, and other extra-market intervention-driven categories, have an increasing role to play in farm structure. They may provide an opportunity for smaller or new operations to gain a foothold in agricultural production. But there are challenges related to producers gaining market access, establishing themselves as selling differentiated products from normal market channels and gaining consumer acceptance as reliable suppliers for products that meet the standards for the specific type of sustainable production. With the possible exception of organic products that are USDA certified, there is no way for consumers to ascertain whether producers met these credence attributes for how the product was produced or to what extent they provided other promised benefits, such as to the local economy, humanely produced, etc. In many instances, sustainability criteria are rather loosely defined. Short descriptions of organic and many other environmentally relevant topics are provided by Osteen *et al.* (2012).

Organic production is the one area of sustainable production that has strict standards for what comprises it. The Organic Foods Production Act of 1990 established requirements for organic production. Subsequent regulations codified a set of criteria that must be met to allow foods to be labeled organic. The USDA has established a certification program to assure consumers that the production attributes promised in organic products have indeed been followed. This is a necessary condition for building trust in such products for which consumers are unable to observe or taste the characteristic they desire. Producers must make the necessary investment of time and resources to comply with the well-defined organic criteria and submit to verification of the practices involved to assure product compliance.

The recent push for local foods has been highly promoted by various interest groups. Local foods can be a challenge to define, and the term is frequently used in conjunction with other sustainable production criteria, including organic. A national standard contained in the Food, Conservation, and Energy Act of 2008 limits local or regional foods to those produced within 400 miles of the market, or within state borders. The local foods category lacks standards that lead to consistency across states or markets, has no strict organizational structure or framework to certify compliance with whatever standards are specified, and has no way to evaluate outcomes (McFadden, 2013). One pragmatic approach is to define local food by the way it is marketed, for example, through farmers markets or through regional food hubs (Low and Vogel, 2011). According to the Census of Agriculture, in 2007 only 6.2% of farms marketed their product directly to consumers for human consumption. Even fewer farms marketed their product through regional food aggregators, although the farms engaging in marketing at that level are more likely to be profitable due to the economies of size advantages.

Overall, sustainable production lacks criteria that provide clarity for what are process-based characteristics. Although there have been various definitions of sustainable used and even defined in agricultural policy through the farm bill, there still remains substantial leeway in what is considered to fall in this category. There has been some interest in using food miles as an indicator of sustainability that could be quantified. However, there is no scientific basis for using food miles as a standard and in fact research has shown that common assumptions about food miles are not valid. Foods produced in highly efficient large-scale operations and transported across the country may be more efficient in economics and environmental impact than locally produced foods from inefficient, small-scale operations, which may use more fuel per unit of product (King *et al.*, 2010).

Nonetheless, this general category of sustainable agricultural production is most likely to continue to expand in the foreseeable future and offer opportunities to smaller producers or new entrants to establish niche production operations. This will allow some of them to compete in the market more easily than in major commodity markets, which are highly competitive and generally require increasing size of operations to remain viable. But as the experience with organics has shown, establishing the stronger criteria to assure product integrity opens the door for larger size operations to compete as well in the niche markets. In fact, many large farms have already established themselves as competitors in these various sustainable market niches, which proponents most likely did not anticipate. Proponents of stronger criteria for organic production perceived the niche as one in which small farms would thrive and provide more environmentally friendly production (Kinsey, 2013).

Aging Principal Operators and Beginning Farmers

As a group, US principal farm operators are older than the typical US household head. In 2011, more than 30% of principal farm operators were of age 65 or older (**Table 4**). The average age of principal operators in 2011 was 58 and has been greater than 50 since at least the 1974 Census of Agriculture. One reason for the advanced age structure of farmers is the farm's status as the family home. Approximately 40% of principal farm operators in the 65+ category reported being retired from farming and 20% had land enrolled in the Conservation Reserve Program. Although principal farm operators less than 35 years of age operate only 4% of all family farms, their farms tend to be larger than those run by older principal operators. A major reason for the small share of farmers who are young is the significant startup costs of a typical farming operation that make it especially difficult to accumulate wealth and acquire control of the land and capital they need. The bulk

Source: Economic Research Service, USDA, based on USDA Agricultural Resource Management Survey, 2011. Author's calculations based on ARMS. Description of ARMS available at: http://www.ers.usda.gov/data-products/arms-farm-financial-and-crop-production-practices.aspx (accessed 29.04.14).

of production from family farms (three-quarters) was produced on farms run by principal operators aged 35–64 years (USDA ERS, 2013b).

For more than two decades, the share of farms operated by beginning farmers – those operating farms on which all operators have 10 years or less experience operating a farm – has been in decline. Beginning farms and ranches account for 22% of US family farms and ranches, and provide 10% of production on family farms. It is natural to assume that most beginning farmers are relatively young. Indeed, when compared with the operators of more established farms, beginning farmers do tend to be younger. The average age of the principal operators of beginning farms in the US was 49 in 2011, compared with 60 for established farms. However, only 14% of beginning farmers were less than age of 35 years in 2011 and just more than half were greater than 50 years (Table 9). Many of the older beginning farmers who come to farming late in life operate very small farms and are more likely attracted to the rural lifestyle that they are able to afford by working at established careers off the farm. Although easily surpassing the 1% of principal farm operators who were less than 35 years of age on established farms in 2011, the low share of young beginning farmers helps to account for the decline in the share of all farms operated by young farmers in recent decades (Ahearn, 2013).

Younger beginning farmers tend to operate larger farms than older operators of beginning farms. In 2011, 11% of beginning operators less than age of 35 years had gross farm sales of $250 000 or more, compared with 6% of those aged 35–49 years and 1% of those aged 50 years and older. As a result, young beginning farm households tend to earn more income on their farm and less off farm than older beginning farm households. Still, more than half of young beginning farmers report losses and, on an average, have much higher debt-to-asset ratios than older beginning farmers. And although beginning farmers less than age of 35 years have more debt than older beginning farmers and have lower average net worth, a higher share of young beginning farmers operate profitable farm businesses. One factor in the viability of young beginning farmers is the degree to which they can cash flow their operations, while growing their operations to a more profitable scale.

Contracting and Supply Chains

Producers operate in a marketing system, which increasingly involves supply chains and contracts for the type of output that retailers need in order to deliver desired products to consumers. In the past, farmers produced and then sold the outputs from their farms through distant markets. That system started evolving in the 1950s to vertical coordination whereby processors or food manufacturers specified contract terms that controlled the types of products they wished to buy and how much they would pay for certain product characteristics. Eventually decision-making power shifted from the food manufacturers and major brands to retailers, who obtained detailed data about consumers purchasing behavior. That information empowered the retailers to determine what is produced and sold (Kinsey, 2013). The supply chain carries value implications at various levels in the production and marketing system but manifests itself at the farm level through production or marketing contracts in order for producers to access market outlets.

Contracting expanded significantly from 2001 and will most likely continue to expand for field crops as larger

operators become more tied in with supply chains that continue to evolve in the agricultural industry. Production contracts specify services provided by a producer, the compensation for the services, and the contractor's role in providing inputs. Production contracts are widely used in livestock production, where 90% of poultry and 68% of hog production were under such contracts in 2008. Poultry producers often specialize and are, therefore, quite dependent on poultry processing contractors, often a single one in a given area that puts the poultry producers at a disadvantage in negotiating contract terms. Hog producers using contracts are generally part of the larger and more diversified farming business, and therefore hog income is not the only source of income from the farming operation. Further, they tend to have alternative contract production outlets (MacDonald *et al.*, 2004; MacDonald and Korb, 2011). Production contracts are also commonly used in vegetable and horticultural crops.

Marketing contracts are used for a number of specialty crops and increasingly in field crops. They specify pricing, or methods to determine price, for product characteristics delivered for a given quantity, but the farmer maintains control of the production process. Crops were sold under contract for approximately 32% of total crop production in 2011; and larger corn, soybean, and wheat farmers using contacting often do so for more than half their crop (MacDonald *et al.*, 2013). Larger farms in general use marketing contracts specifying product attributes delivered for a substantial share of their production as one form of risk management for their operation. One example is provided by tobacco and peanut producers who shifted to contracts following termination of Federal marketing programs, which for years limited their price risks (McDonald and Korb, 2011).

In addition to supply chain contracts in the marketing function, some producers – outside the prominent production contracts in poultry and hog supply chains – contract for certain production inputs. One example is the role of labor contracts as an important element of large-scale specialty crop production. Rather than hiring individual workers, the farms often rely on firms specializing in providing the needed labor over the crop season. In 2009, there were 14 103 firms that provided agricultural labor support, including machines, employing 292 000 wage and salary workers. Out of those, 2166 firms provided 149 546 field workers and crew leaders (U.S. Bureau of Labor Statistics, 2013).

Policy Role in Farm Size and Structure

How US agricultural policy, various regulatory policies, and international trade policy affect farm size and structure are ongoing concerns and are subject to potential change. They have previously and will likely continue to influence the structure of agriculture and farm size.

Government Payments

Current US agricultural policies are rooted in the 1930s and have been redesigned over time, currently approximately every 5 years. Commodity and conservation programs are a major feature of farm policies and include payments to farmers and farmland owners who are eligible for a variety of programs offered at any one time. Most commodity program payments go to larger scale operations, whereas many of the conservation land retirement payments, such as the Conservation Reserve Program designed to protect fragile lands in permanent crops or trees go to smaller operations. Commodity programs – primarily providing subsidies for food and feed grains, cotton, and oilseeds production – are based on the amount of cropland enrolled, currently or historically, and yield history. They comprised approximately 75% of all government payments to farmers in 2007. The commodity programs exclude most specialty crops as well as livestock, although these latter producers may receive periodic disaster payments authorized by Congressional action. Some nonprogram commodity and livestock producers may still receive payments based on program commodities that they also produce currently or did in the past (Hoppe and Banker, 2010).

Conservation payments are available to a much wider range of producers, with nearly all crop and livestock producers eligible for at least one conservation program. See Hoppe and Banker (2010) for a brief description of the various types of farm program payments. As shown in **Table 10**, 35% of all farms received government payments in 2011. The large farms, with US$250 000 or more in sales, received approximately 60% of all payments. Given the design of the programs, 77% of the commodity program payments were received by the 10% of farms classified as large farms. In contrast, the large farms received a smaller share of conservation payments, or 35%. The largest conservation program is the Conservation Reserve Program, which requires that working land is put into conserving uses to maximize environmental benefits.

Subsidized crop insurance is the other major government program. Originally targeted to crops covered in the farm bill commodity programs, it has become more widely used for a broader range of agricultural commodities. In 2010, the program covered 255 million acres, with four commodities – corn, soybean, wheat, and cotton – accounting for three-quarters of those acres. As most of the acreage in these commodities is on large farms, the majority of participating farms are larger farms. Under the program, the producer pays a share of the premium and the government subsidies the rest. Currently, the government share is approximately 60%. Unlike other government farm programs at the present time, crop insurance premium subsidies have no means testing against participants' income levels nor is there a total payment limit. The cost to taxpayers of heavily subsidized crop insurance has steadily increased – from US$2 billion in 2001 to US$9 billion in 2011. The current budget projections are for spending on crop insurance to outpace spending on traditional commodity programs over the next 10 years (Shields, 2010).

Regulations

Producers are subject to or affected by an increasing array of regulations – including environmental, conservation, food

safety, and trade regulations. All of these have potential to impact the structure of agriculture, as farms adjust to comply with the regulations.

Some of the more prominent and contentious environmental regulations of the US Environmental Protection Agency involve the Endangered Species Act, the Clean Water Act, and the Concentrated Animal Feeding Operations Act. These three acts have been the source of ongoing conflict between farmers and those concerned with potential impacts on various species and on water and air quality. Lawsuits have been frequent and are more likely to continue. In contrast, USDA programs to promote good environmental stewardship have involved paying farmers and farmland owners to adopt good practices. Not too surprisingly these are less contentious because they are voluntary and involve payments. However, participation in some commodity programs requires cross-compliance with environmentally sound practices and even these requirements have been controversial at times.

Ecosystem services is a concept receiving increased attention and in many ways represents a coalescing of issues encompassed in environmental and conservation regulatory programs. To the extent that agriculture is required to meet more stringent environmental regulations to protect ecosystem services provided by the environment to agriculture and by agriculture to the environment for enjoyment by other citizens, producers will more likely face increased costs. Unless exemptions are made for smaller operations, such regulations are more likely to provide incentives for further consolidation of production into larger operations. The typical expectation of exemptions for smaller operations may not be realized, given that larger operations may be able to better manage and monitor outcomes of their practices designed to minimize any damage to ecosystems from the farming operation.

Food safety has become a much more prominent issue in recent years as consolidation within the food industry has increased the likelihood of a food safety event affecting many states or a wide area, rather than being more localized as was earlier the case. Most recently, the FSMA of 2010 updated the food-related elements of the Federal Food, Drug, and Cosmetic Act administered by the Food and Drug Administration (FDA). It significantly expanded authority of the FDA related to food regulation, including authority to mandate recalls of contaminated food products to replace what had been a voluntary system. However, the FSMA does not cover the USDA-regulated meat, poultry, and egg products. It is possible that additional legislation will bring the USDA-administered food safety programs into alignment with the FSMA, but that remains to be seen. Meanwhile, the FSMA has implications for costs to farms that will need to adopt more stringent good agricultural practices to meet expectations of the food handlers and processors facing requirements to adopt HAACP systems at all levels in the food supply chain. See the earlier discussion of Consumer Preferences under Additional Drivers of Change in Structure and Organization for potential implications of the FSMA for farm structure and organization.

Trade regulations, including World Trade Organization (WTO)-negotiated and individually negotiated bilateral or multilateral trade agreements between the United States and one or more countries, often contain provisions that limit farm program payments to producers. They provide interesting dilemmas for long-standing US commodity programs, which in some cases have been challenged in the WTO and under other trade agreements. Several of those cases have been lost by the United States and farm programs had to be adjusted or are still to be brought into alignment with the decision's required or proposed remedies. In some instances, the US programs have continued unabated and fines were paid in lieu of changing the program. In others, adjustments have been made that resulted in farmers being more exposed to market price risks. To the extent that future negotiations or dispute settlements eliminate farm program protections, the need to manage risks may lead to greater consolidation of production into larger units more capable of such risk management.

Future Challenges

The preceding data, trends, and discussion suggest a number of issues that will affect the future of agriculture's structure, profitability, and role in the US and world economies. Some issues are internal to the agricultural industry, whereas others are driven by consumer interests and concerns, environmental factors, and domestic and international trade policies. Managing the challenges of the several risks discussed below cuts across the range of these issues.

Climate Change

To the extent that scientific expectations about climate change leading to more variable and severe weather events are accurate, weather risks faced by producers are more likely to be greater in coming years. This will provide incentives for producers to adapt crops they cultivate through adopting improved varieties designed to better cope with weather events, such as prolonged drought, excessive moisture, or extreme heat, or even to change crops produced on their farms. Further, shifts in climatic zones create the potential for costly pest problems from plant and animal diseases, invasive weeds, insects, microbes, and fungi that spread to new geographic areas.

Climate change, along with other challenges discussed here, will put a premium on risk management at the producer level, either through insurance programs or through other risk management strategies, such as futures market hedging and crop diversification. These factors will continue to provide incentives for growth in size of farming operations to spread the costs of insurance, hedging, and crop diversification over larger acreages and output.

Technology

Technology will most likely continue to evolve – including genomics and other branches of biotechnology that will most likely have major implications for plant and animal breeding – and hence farm size increases are to be expected. New technologies typically are expensive, at least in the early stages of implementation, and this creates an incentive for farmers to spread the cost over larger acreages. Although some technologies are truly size neutral, such as genetically modified

seed, many are too expensive for smaller to medium sized operations to economically adopt. This suggests that public opinion about the structure of agriculture may influence future R&D funds to be allocated somewhat differently to assure that research results are more truly size neutral.

Increasing total factor productivity has meant that individual farm sales have expanded rapidly due to technological changes adopted at the farm level. This trend has been a major contributor to the increasing size of farm operations and the phenomena of a small percent of total farms producing the vast majority of agricultural output. However, a critical issue is to what extent future public sector support for agricultural productivity enhancing research will be at levels sufficient to keep the United States competitive in a global economy in which emerging countries are investing heavily in this type of research. There are heightened concerns in the agricultural science community that the United States and other developed countries are underinvesting in public agriculture R&D (Executive Office of the President, 2012).

Food Safety

Supply chains designed to deliver retail-level products with characteristics that consumers desire have expanded significantly as an organizational tool in the agricultural and food industry in recent years. Further processing of most food products, including even raw produce processed into more convenient product forms ready for the table or food service use, makes food safety a constant concern in the food supply chain. To successfully compete for opportunities in the supply chains, producers are required to adhere to strict food safety guidelines incorporated into contracts within the supply chain for products delivered to the next level. This facilitates traceability from the consumer back to the farm level of any products that may cause foodborne illness outbreaks. Thus, it may be expected that more use of HAACP-type programs will be required of supply chain participants even at the farm level, and the expense of such systems will be at least in part absorbed by the producers. This will provide further incentives for growth in farm size to spread the costs involved over larger amounts of product.

Globalization

Ongoing growth of emerging market and developing country demand will create an opportunity for more US exports. It may also open the door to more imports into the United States from new production areas designed to serve expanding markets. Globalization will continue to create challenges, as witnessed by the current international debate on the acceptance of genetically modified agricultural products. But even with increased globalization, domestic agricultural policy will remain a major factor impacting farm size and structure in the foreseeable future.

The extent to which the US producer thrives from developing market opportunities will depend at least in part on trade negotiations and the implications for US domestic agricultural policy and products. It will be important that the United States maintain strong food safety standards for any products imported and meet the food safety requirements of other countries in order to gain exports. Trade negotiations will need to help establish guidelines about the types of food safety or other requirements countries may impose on product quality characteristics, so that standards are not established, which are designed primarily to create a nontariff barrier to imports from the United States or other countries.

Concluding Comments

The future size and structure of US farms, number of farms and farmers, and the relative economic prosperity of agriculture will be determined by the factors identified above and others. Similar changes are to be anticipated in most developed countries and in those developing countries with large commercial farming sectors. The next few decades will most likely see changes that have similar impacts to those experienced over the past several decades. The exact nature of the changes, the structural implications, and the opportunities created for farmers to provide food, feed, fiber, and fuel profitably will be determined by market forces, social systems, climatic conditions, environmental and other regulations, and agricultural and trade policies, among other factors. It will be an exciting time to be involved in the globally connected agricultural sector.

Climate Change: Agricultural Mitigation

M van Noordwijk, Jalan Cifor, Bogor, Indonesia

© 2014 Elsevier Inc. All rights reserved.

Glossary

Adaptation Adjustment to changing conditions (including climate change); can refer to adjustment during the lifetime of an organism or system or to cross-generational genetic changes.

Additionality The environmental impact, for example, emission reduction, achieved in comparison to a 'business as usual' development pathway.

Agriculture, Forestry and Other Land Uses (AFOLU) Intergovernmental Panel on Climate Change guidelines for accounting of land-based greenhouse gas emissions (successor to the land use, land-use change, and forestry guidelines, but not yet formally accepted by United Nations framework convention on climate change (UNFCCC)).

Clean Development Mechanism Part of the Kyoto accord of the UNFCCC

Intergovernmental Panel on Climate Change The science/policy boundary organization that reviews evidence on climate change in a 5-year cycle of reporting.

Land use, land-use change and forestry Guidelines for accounting of land-based greenhouse gas emissions (superseded by AFOLU).

Leakage The unintended effect on emissions elsewhere (beyond the project scale).

Mitigation (in context of climate change) Reducing the net emissions of greenhouse gasses to the atmosphere.

Value chain A representation of a sequence of actions that transform raw materials (or land use enhancing C sequestration) into marketable products (certified emission reduction) that an end user could buy.

Introduction

Perspectives on agricultural mitigation have evolved from the first report of the Intergovernmental Panel on Climate Change (IPCC) (Sauerbeck, 1993), through the second (Cole *et al.*, 1996; Paustian *et al.*, 1997), third, and fourth (Metz *et al.*, 2007; Smith *et al.*, 2008) to current discourse (Ericksen, 2008; Beddington *et al.*, 2012; Burney *et al.*, 2010; Vermeulen *et al.*, 2012; Baker *et al.*, 2012; Neufeldt *et al.*, 2013). There has been (1) a refinement of numbers on current emissions and their sources, with agriculture currently responsible for 11% of global emissions (UNEP, 2013), (2) more integration in scenario modeling than cross sectoral borders (Golub *et al.*, 2009), (3) responses to some of the accounting system anomalies that allowed global emission displacement around biofuels to be counted as emission reduction, (4) separate efforts to deal with forestry emissions under the REDD+ (efforts to reduce emissions from deforestation and forest degradation) agenda that showed the challenges of a partial approach in what is an integrated landscape (van Noordwijk *et al.*, 2013), and (5) a greater appreciation of action opportunities on the demand side of the equation. Part of the food system industry is responding to consumer action and demand for low-carbon-footprint products, whereas formal governance systems and international negotiation arenas are slow to respond effectively. Current global greenhouse gas (GHG) emission levels are already considerably higher than would be allowed in 2020 in scenarios that keep global warming below a 2 °C target (UNEP, 2013). Experiments with carbon markets have captured the imagination beyond actual performance, but there certainly are considerable opportunities to reduce net GHG emissions while meeting rising global demands, compared to a 'business as usual' extrapolation of past trends. The challenge is how to provide economic incentives for 'clean development' across scales, without a huge bureaucracy and network of intermediaries whose pay and transaction rents compete with real actions on the ground. This article starts with defining the scope of mitigation and agriculture, before reviewing current emission estimates of the three main GHGs involved – nitrous oxide (N_2O), methane (CH_4), and carbon dioxide (CO_2) – across the agricultural spectrum, and discuss how projected increases in demand from a growing and more wealthy global population can be reconciled with emission reduction in macro-level scenarios. Finally, this is followed by considering the experiments with micro-incentive systems currently under way. Although there is a wealth of studies and syntheses in the technical literature, the focus here will be on bridging the 'supply' and 'demand' side approaches to achieve the overall objective of the United Nations Framework Convention on Climate Change (UNFCC) (UNFCCC, 1992) as stated in its second article, to 'stabilize GHG concentrations in the atmosphere at a level that would prevent dangerous anthropogenic interference with the climate system.' As one would note, there are several weaving errors in the regulatory tapestry set up for achieving the UNFCCC objective, made up of a warp of countries, a weft of sectors, and shades of colors ranging from mitigation to adaptation and vulnerability. As will be discussed below, neither the terms 'mitigation' nor 'agriculture' as defining concepts are as clean and clearly separated from other aspects as it might appear.

Mitigation as Part of the Climate Change Discourse

Mitigation Plus Adaptation

The term mitigation originally meant softening, as it is derived from the Greek mitis=soft, rather than from the kiSwahili

 doi:10.1016/B978-0-444-52512-3.00002-4

miti = forest. It has obtained a specific meaning in the international climate change discourse: it has become shorthand for reducing the net emissions of GHGs to the atmosphere that are seen as the primary drivers of global climate change, because such climate change is considered a risk for humanity and the future of planet Earth as known. Mitigation was defined as the primary line of defense in the chain of events (Figure 1) that caused a reduced quality of life due to the human activities that induce an increase of atmospheric concentrations of GHGs. The atmospheric concentration of GHG's, net result of emissions and uptake by oceans and terrestrial systems, together with solar irradiation, reflection (albedo), and hydrological cycle shape the climate system; the current rate of change will soon bring us beyond the safe planetary boundaries of our coping range (Rockstrom *et al.*, 2009). This will lead to direct human vulnerability and to indirect effects on human welfare through ecosystem changes. Adaptation is a second line of defense, which reduces vulnerability in the face of exposure to change, but which implies a failure of the UNFCCC to achieve its primary target. Adaptation shifts the concept of what is 'dangerous,' but does not reduce interference with the climate system. Nor can it deal with the risks of run-away, positive feedback loops such as changes in ocean current systems, inducing further change once thresholds are crossed. One does not know exactly where those thresholds are, so the precautionary principle should be applied (Ramanathan and Feng, 2008; Rockstrom *et al.*, 2009). Early warning signs of real change have been around for at least two decades (Smith *et al.*, 2009). Synergy between mitigation and adaptation is feasible in land use (Verchot *et al.*, 2007; Smith and Olesen, 2010).

Direct Micro- and Meso Climate Forcings?

There is an alternative perspective to the conventional cause–effect-impact relationship between agriculture and climate. It does not solely or even primarily relate to the global GHG effects – as indicated a bypass to the macroclimatic GHG route (Figure 1). Pielke *et al.* (2007) discussed the diverse local and regional climate forcing that impact agricultural systems and represent effects of local land cover change and aerosol production on local climate and geographically explicit

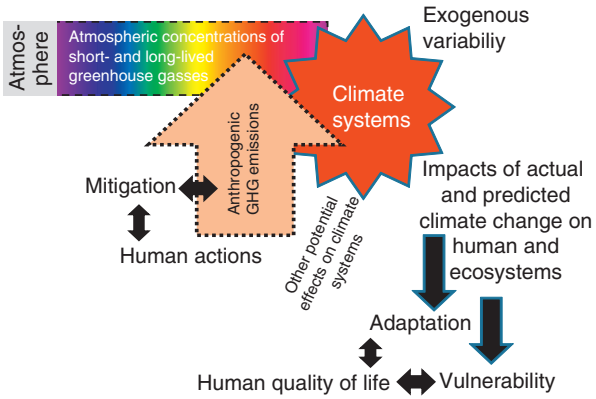

Figure 1 Feedback loop from human actions via GHG emissions to climate change, impacts on human and ecosystems and vulnerability and ultimately quality of life where these impacts exceed the coping range, potentially adjusted by adaptation measures.

teleconnections, relationships between local effects and distant but geographically explicit causes. In their view, agricultural assessments of risk to climate change and variability should start with a bottom-up perspective of understanding local climate, as a complement to global top–down modeling. Actions to mitigate climate change may similarly be seen from a new angle if a coadapt approach is taken (van Noordwijk *et al.*, 2011) that allows for local actions with local effects to add up to global impacts; tree effects on the microclimate of agriculture begin to get recognized (van Noordwijk *et al.*, 2014c). New perspectives on 'rainbow water' that relate terrestrial evapotranspiration to rainfall elsewhere on the same continent showcase specific teleconnections (van Noordwijk *et al.*, 2014a).

Accounting for Anthropogenic Emissions per Area, Activity, Capita, or Sector

The concept of anthropogenic interference with climate systems is an aggregate that needs disaggregation before it can be dealt with. This is where the problem starts. The totality of emissions can be derived from summing over all people and their per capita emissions, from summing over all land areas and the change that occurs per unit of space or from summing over all sectors and subsystems of human activity:

$$\text{Anthropogenic interference} = \mathrm{f}(\Sigma \mathrm{E}_{\mathrm{GHG}}) = \mathrm{f}(\Sigma_i E_{\mathrm{GHG},i}) = \mathrm{f}(\Sigma_j E_{\mathrm{GHG},j}) = \mathrm{f}(\Sigma_k E_{\mathrm{GHG},k}) = f(\Sigma_n E_{\mathrm{GHG},n}) + M \quad [1]$$

where i sums over all pixels (units of space) on planet Earth, j over all people and their per capita emissions and k over all sectors and types of human activity with associated footprints. The summation over all nations n requires an additional term M for the international waters and international transport that are not otherwise attributed.

In principle, the first three approaches can all lead to a consistent result. However, what we currently have in the policy debate is a hybrid, which contains elements of all three (national emissions, per capita calculations, and product footprints), but is at risk of double-counting as well as having gaps. Although emissions are of primary interest, which are fluxes, there are good reasons to approach them through changes in directly observable stocks (e.g., carbon stored in soils or vegetation) for part of the accounting system, but again hybrids of flux and stock accounting are problematic. Linked to the United Nations framework in which the UNFCCC was developed, nation states are the primary accounting units. This implies primarily a territorial and citizen-based approach to accounting, but has challenges with multinational companies, international (cross-border) trade and is trapped in a political dichotomy of 'developed' versus 'developing' countries (diplomatically termed 'Annex I' vs. 'Nonannex I'), where the major share of emissions shifted to transitional economies such as China (Peters *et al.*, 2011). In absolute levels, developing (and transitional) countries accounted in 2010 for approximately 60% of global GHG emissions (UNEP, 2013). Davis and Caldeira (2010) estimated that 23% of global CO_2 emissions (6.2 Pg CO_2) were traded internationally, primarily as exports from emerging markets to consumers in developed countries. Sharing

responsibility for emissions embodied in trade among producers and consumers could, in their view, facilitate international agreement on global climate policy – agreements now hindered by concerns over the regional and historical inequity of emissions. The emissions embodied in trade concept also applies to agriculture and associated global trade flows (Minang *et al.*, 2010). For example, local nutrient cycles became global nutrient flows (van Noordwijk, 1999), with continued dependence on new inputs and associated GHG emissions.

Footprint Accounting

In the face of the failure of the nation states to achieve convincing collective action at par with the challenge, a global citizen-based approach has emerged with attention on the 'footprint' of all goods and services that they use for their lifestyles and diets (Pandey *et al.*, 2011; Peters, 2010). This follows from a simple disaggregation of the citizen based accounting system:

$$\mathrm{f}(\Sigma_j E_{\mathrm{GHG},j}) = \mathrm{f}(\Sigma_s \Sigma_m P_s * L_{m,s} * F_m) \quad [2]$$

where P is human population size per social stratum s, L is lifestyle and per capita use of goods and services for social stratum s, and F is the footprint or emissions per unit goods and services (indexed m). Controlling P is a politically sensitive and religiously contested domain for public policy, and investment in access to education for girls may well be the only widely supported long-term approach. There is a large current disparity between social strata in L and there are valid aspirations to increase the average under the heading of 'development.' That leaves F, or the efficiency with which goods and services are produced, as the primary degree of freedom. Increasing efficiency is a potential win-win solution in many environment/economic tradeoffs.

Territorial, Sectoral, and Demand-Based Interpretations of 'Agriculture'

Turning now to agriculture, elements of all accounting approaches are seen coming together, with several challenges for transparent and comprehensive accountability. Agriculture uses land – but as a land use category it has a fuzzy boundary with 'forestry' (Watson *et al.*, 2000), as well as with 'wetlands.' These three land uses are adjacent chapters in the Agriculture, Forestry and Other Land Uses accounting system designed by IPCC (2006). Agriculture uses inputs such as fertilizer and machinery, which are derived from mining and manufacturing industry, as well as fossil fuels for farm operations and transport of products. In a sectoral approach these need to be accounted in one, and only one sector. However, farm-level decisions about alternative approaches then have cross-sectoral consequences that require consistency of policies across the various sectors involved. Agriculture is the basis of a food supply systems, with considerable waste along the chain, as only a fraction of the food that is produced is consumed (Parfitt *et al.*, 2010). What part of the food wasted is attributable to agriculture, what part not? Agriculture together with forestry provides a large share of the fiber supply systems with textile, paper, and other applications that also have fossil fuel–based alternatives. Jointly the two are still the primary source of energy for a large share of the rural population, with options to substitute firewood, charcoal, and dried-manure by fossil fuel use. On the other side of the spectrum, agriculture- and forestry-based biofuels resubstitute for fossil fuel. Emission reduction in one 'sector' can be achieved by shifting product flows and associated emissions to another sector, without decreasing the anthropogenic interference with the climate systems. The sectoral map of the world has dotted lines as boundaries (**Figure 2**). Rigidity of concepts such as an agriculture concept that does not allow overlap with forestry, as in Food and Agriculture Organization databases, is thus seriously challenged to deal with trees outside forest and agroforestry as intermediate land use system (de Foresta *et al.*, 2013). Rigidity implies considerable cost to the rationality of decisions based on them.

Multiple Perspectives

Compared to the discussions on 'Mitigation in Agriculture' in the first IPCC report (Sauerbeck, 1993), the current discourse (Beddington *et al.*, 2012) has brought greater recognition for the demand side, with attention to waste and lifestyle choices of human diets. It also acknowledges that there are planetary boundaries to ambitions for all to emulate the American dream and diet. Thus the current debate encompasses multiple aspects, accounting principles, and outstanding issues of agriculture (**Table 1**).

There may be a general trend to move from an area-based emissions per unit of agricultural land, to efficiency/footprint-based concepts (emissions per unit end-user satisfaction with goods and services), but these still have an area-based component in the calculation. Consequently, it requires productivity data. A concept of 'indirect land use change' that has emerged in the biofuel debate (Plevin *et al.*, 2010) applies to any new or existing crop and is a challenging one. To what degree can a new use of a crop be held accountable for the additional conversion of land into agriculture elsewhere in the world? Will the new use have left some of the original demand unmet? Is every parcel of land that once supplied a product for a certain type of use bound to keep going that forever? With such concepts we appear to be trapped in the rigidity of artificial accounting concepts and need to go back to the basics of the totality of anthropogenic interference with climate systems. All this leads to a hot debate about the optimum level of intensity of land use, in the face of the nonlinear relationship between inputs, emissions, and yield per unit area (Doré *et al.*, 2011; Jackson *et al.*, 2010, 2012; Matson *et al.*, 2012). As intensification influences various aspects of the accounting system, optimization from a GHG perspective can only be done at national aggregated level. In terms of GHG accountability, a focus on imports rather than local food production is a very attractive choice at national level – similar to the transfer of high-emission industries to countries without emission reduction commitments. However, from an atmospheric impacts perspective, focus should be on reducing the total of net GHG emissions directly or indirectly associated with the sum total of global agricultural production.

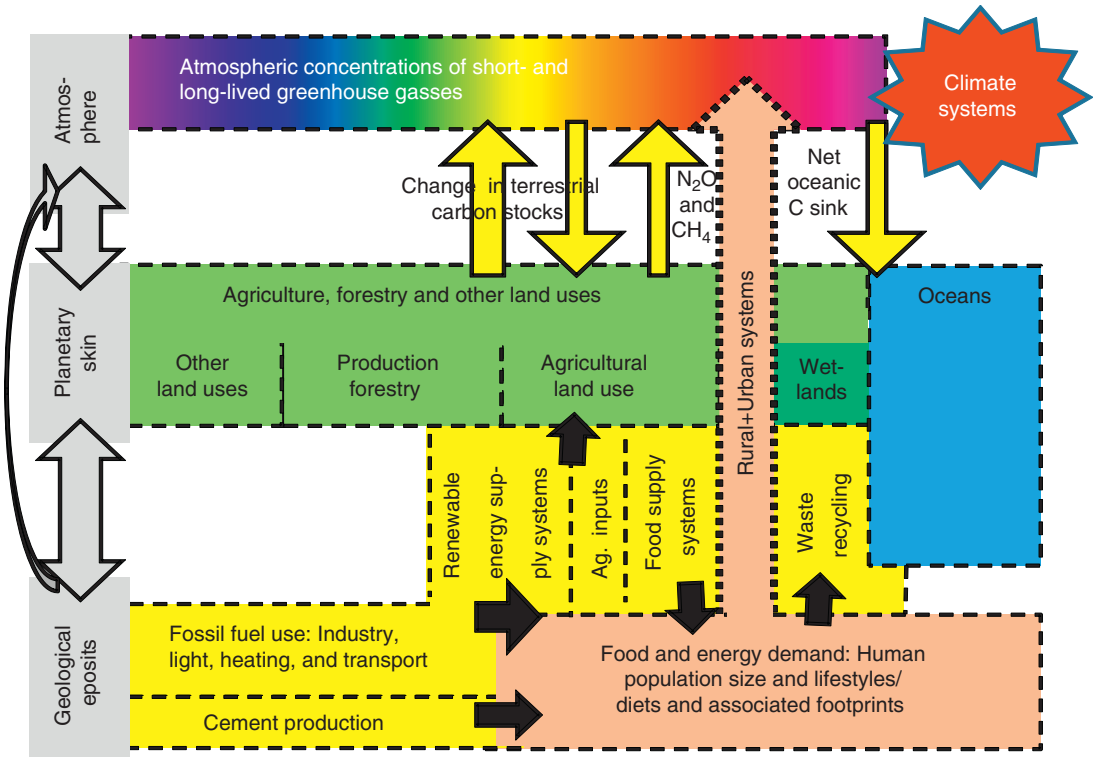

Figure 2 Agriculture as part of the anthropogenic GHG emissions: It relates not only to an important part of land use (interfacing with forests, wetlands, and oceans as basis for food supply systems, as well as energy supply systems), but also with direct energy consumption for agricultural inputs and transport, and with (missed opportunities) for waste recycling; ultimately agriculture responds to the shifts in demand, that are based on human population size multiplied with the goods and services required for lifestyles and diets, modified by the footprints per unit good and services.

Current Emission Estimates

In 2008, agricultural production, including indirect emissions associated with land-cover change, contributed 80–86% of total food system emissions. This was 19–29% of global anthropogenic GHG emissions, releasing 9.8–16.9 Pg of carbon dioxide equivalent (CO_2e) to the atmosphere (Vermeulen *et al.*, 2012).

CO_2, N_2O, and CH_4 Compared

The 'greenhouse effect' impacts of nitrous oxide and methane can be expressed in carbon dioxide-equivalent quantities based on their global warming potential. This includes the direct heat trapping effect of the gasses as well as their expected residence times in the atmosphere. Conventionally, a hundred-year time frame is used in defining the default CO_2e values per unit N_2O and CH_4 at 296 and 25, respectively, Evaluated over shorter time frames, the global warming effect of CH_4 would be rated higher.

Forest-to-Agriculture Conversion

Agriculture and the size of the human population have risen as a consequence of deforesting the earth to create farm land (Williams, 2006; Gibbs *et al.*, 2010). The logarithm of human population size accounts for 70% or more of the variation in forest cover at national and subnational scales, with 80% of data within plus or minus 10% of the predicted forest cover. However, the emission consequences of this conversion differ by the carbon density of the natural forest and the specific pathway of change, which can be gradual or direct; but the net effect on CO_2 emissions does not depend on the pathway taken. Yet, 46% of the agricultural lands have at least 10% tree cover (Zomer *et al.*, 2009), and trees are compatible with agricultural production (de Foresta *et al.*, 2013). Fortunately, simple approaches to quantifying the net carbon loss from change in tree cover are available (Hairiah *et al.*, 2011), compatible with IPCC (2006) guidelines. Methods for other GHG emissions are also becoming simpler (Milne *et al.*, 2013). The net emissions per unit agricultural product vary along the forest or tree cover transition curve (Rudel *et al.*, 2009; Meyfroidt and Lambin, 2011), depending on the preceding land cover that was converted and on how far back in history the accountability rules apply.

Soil Carbon Transition Curves

Soil carbon stocks express a balance between organic inputs and their stepwise decomposition by soil biota. The stock ($tC\ ha^{-1}$) can be estimated as the sum over annual inputs ($tC\ ha^{-1}\ year^{-1}$) multiplied with mean residence time (year)

Table 1 Multiple perspectives on agriculture in relation to mitigation issues

Perspective on agriculture	*Accounting principle*	*Challenges*
1. Agriculture as land use, modifying above- and belowground C stocks in comparison to forests and wetlands and increasing or decreasing methane emissions	Area-based emission accounting as per AFOLU (or its predecessor LULUCF; for CO_2 emissions this is primarily based on change in above- plus belowground stocks, for N_2O and CH_4 on summation of fluxes	What about trees outside forest and agroforestry? What about anthropogenic reduction of natural (e.g., wetland) ecosystem emissions?
2. Agriculture as transformer of solar energy + CO_2 + water + nutrients into usable organic matter + waste + N_2O + CH_4	N_2O emissions from agriculture are estimated as fraction of total fertilizer use	What about N_2O emissions based on biological N_2 fixation or organic fertilizer inputs?
3. Extensive rangelands grading into natural ecosystems, as start of intensification	Accounting per unit livestock, CH_4 emission profiles depending on feeding regimes	N-rich feeds reduce CH_4 emissions per animal, but increase N_2O emissions of the manure
4. Relations with oceans, coastal and freshwater fisheries, aquaculture, and animal feed stocks	Productivity and CH_4 + N_2O emissions are accounted separate from the nitrogen and phosphorus transfers from agriculture that influence them	International waters remain outside of any accounting system
5. Agriculture as driver of transport and input industry	Transport emissions are accounted outside the agricultural sector	Can locally produced biofuel, be counted as carbon neutral?
6. Agriculture as basis of food system value chains, responding to demand signals	Footprint concepts and efficiency of output in usable products per unit emissions. Nonutilized production as consequence of supply-demand mismatch is not handled separately	Where does accountability of agricultural sector end and that of other parts of the food system take over?
7. Agriculture as potential basis for 'bioenergy,' recyclable 'waste'	Domestic use of biofuel or methane capture from waste recycling is accounted through its reduction of fossil fuel dependency Where international trade is involved and products cross borders, ad hoc footprint efficiency criteria apply to bioenergy feed stocks	Attempts have been made to include international wood trade into the system, and the same might apply to other organic exports, but this creates loopholes and inconsistencies

similar to tree cover transition. Conversion into agriculture reduces annual inputs, as more of the carbon gets exported from the field with harvested products, whereas it reduces the mean residence time as tillage speeds up decomposition and mineralization. With a switch in management practice a soil carbon transition can be induced similar to the tree cover transition. Such transitions can also result from increased cropping frequency and associated root inputs to the soil (Minasny *et al.*, 2011; van Noordwijk *et al.*, 2014b).

Livestock

Livestock is accountable for emissions both through the way feed is produced with consequences for changes in C stocks and N_2O emissions and though methane emissions at the animal level that depend on feed quality (IPCC, 2006; Herrero *et al.*, 2009, 2010). In the context of global land cover data, the handling of the transition from grazed dry forest to wooded savanna and to rangeland with trees is a challenge for consistency: with seminomadic and transhumance livestock systems being more easily accounted per head than per area grazed. Deforestation in the humid forest zone of Latin America has been historically dominated by extensive livestock production, whereas in Africa *Trypanomosiasis* prevented similar livestock systems, whereas in Asia the regional supply/demand situation did not make such conversion attractive.

Rice Paddies

Methane emissions by cultivated paddies or natural wetlands is the net result of methane production in the anaerobic zones of submerged soils by methanogens, and its oxidation into CO_2 by methanotrophs in the aerobic zones of wetland soils and in upland soils (Le Mer and Roger, 2001). Net methane emissions can be approximately 10 mg CH_4 m^{-2} h^{-1}, whereas methane oxidation by aerobic upland soils (forests are most active) is two orders of magnitude less. Submersion and organic matter addition increase methane emissions. Intermittent drainage and utilization of the sulfate forms of N-fertilizers reduce CH_4 emission (Le Mer and Roger, 2001). Conversely, the methane oxidation potential of upland soils is reduced by cultivation, especially by ammonium N-fertilizer application.

Peatland Use

Globally, peatlands store more than half of total soil carbon. Both in the northern temperate and tropical zones peatlands are in agricultural use, with annual emissions per unit area that are a factor 100 or more above those on mineral soils. Peatland emissions derive from the use of fire in land clearing, the increased decomposition due to drainage and fertilization. Together these make the organic residues that took thousands of years to accumulate disappear in one or a few decades.

Where natural and disturbed wetlands and peats emit methane, methane oxidizers become effective once the water table is below 30 cm of the soil surface. Conversion of tropical peatland for plantation crops such as oil palm has become a major issue Agus *et al.* (2013).

Projected Increases and Relevance of Demand-Side Adjustments

Shifts in Diets and Lifestyles

The recurrent debate on how a human population of 9 billion can be fed with sufficient and sufficiently nutritious food has different answers depending on the degree of freedom in dietary choice that is assumed for future generations (Nelson *et al.*, 2010; Shindell *et al.*, 2012). Poverty reduction and expansion of a middle class has large consequences for the composition of the human diet, and its associated emissions and waste (Beddington *et al.*, 2012; Parfitt *et al.*, 2010). The different dietary options to meet daily human needs have very different footprints in terms of carbon and other GHG emissions.

Although there are broad patterns associated with product food groups and their trophic position, there can be a considerable 'management swing potential' (Davis *et al.*, 2013) that differentiates the best from the worst management practice in the production of goods that are otherwise indistinguishable. For example, palm oil can be both the best and the worst vegetable oil in terms of carbon emissions per unit product, depending on whether it is grown on peat or mineral soil, and whether the deforestation history of the site is still attributed to the current plantation. This equally applies if such palm oil would be used as biofuel source, rather than for the food industry, but focus of the debate has been disproportionally on such potential biofuel use.

Although a more vegetarian lifestyle and diet has substantial benefits in reducing footprints, its direct consumption of soybean, rather than via an animal stage in a food chain, does not release it from the issues around the soybean carbon footprint that are primarily attributable to direct and indirect land use change (van Middelaar *et al.*, 2013)

Bioenergy on the Agricultural Accounting Plate?

Within the UNFCCC accounting rules, one of the simplest ways to meet emission reduction obligations is to move high-emission industries, such as agriculture, across the accounting border. As land-based products can be subsequently used as biofuel and reduce dependency on fossil fuels without a change of lifestyle or transportation systems, a very attractive pseudosolution became available to policy makers. Crutzen *et al.* (2008) pointed to this accounting anomaly in the case of biofuels, and there have been several attempts since to redress the issue.

If a substantial part of global energy needs in the future are to be met by biofuel sources, the land required for agricultural production may double – which shows the level of challenge involved. Although there have been hyped expectations of miracle biofuel crops that can be highly productive on marginal soils without dependency on inputs, reality is otherwise, as many farmers have learned the hard way (Iiyama *et al.*, 2012).

Technical Opportunities for Efficiency Gain Plus Emission Reduction

Vermeulen *et al.* (2012) estimated agriculture's net GHG emissions along the food chain as:

- 3.8–5.2% due to production of fertilizer, pesticides, and feed transport (mostly CO_2).
- 40.8–55.7% due to direct emissions in production stage (mostly N_2O and CH_4).
- 23.9–43.8% due to indirect emissions and initial land conversion (mostly CO_2).
- 10.2–16.7% due to postproduction processing, transport, and cooling (CO_2, N_2O, and CH_4).

Opportunities to reduce emissions exist throughout the chain, with the direct and indirect emissions offering the largest reduction options. The author will first focus on the direct emissions.

Reducing the Temporary Excesses of Available Nitrogen that Allow for High N_2O Emissions

Mosier *et al.* (1998) and more recently Reay *et al.* (2012) found current N_2O estimates to be reasonably consistent at the global scale between accounting for measured atmospheric change and known emission sources, but that a lack of direct measurements makes national and subnational estimates highly uncertain. Although continued intensification of existing lands is essential in meeting future needs (Matson *et al.*, 2012; Zhu and Chen, 2002), increased nitrogen nutrition of crops is needed. However, options exist to achieve that without increasing nitrous oxide emissions by increased N uptake efficiency at the farm scale, although these require appreciation of spatial heterogeneity in fields currently managed as if they were homogeneous (van Noordwijk and Wadman, 1992; Gebbers and Adamchuk, 2010; Cao *et al.*, 2012). Expanding the buffer zone between nutrient excess and deficiencies in access is crucial (van Noordwijk and Cadisch, 2002) and requires location-specific solutions to increase synchrony, synlocation, and buffering (Hillier *et al.*, 2012). In the transition from a primarily nutrient-constrained agriculture (Giller *et al.*, 2006), overshoot into excessive fertilizer use is likely and leads to situations where emission reduction by reducing N fertilizer use can both increase yields as well as economic returns from farms (Kahrl *et al.*, 2010). For N-rich regions in China, 15% of N fertilizer can be saved without yield loss, by increased nutrient use efficiency, whereas in N-poor regions of the same country, additional N fertilizer use would benefit yield (Wang *et al.*, 2011b; Yunju *et al.*, 2012).

Reducing CH_4 Emissions by Better Feeding Regimes of Ruminants

Methane emissions from ruminants are a consequence of an excess of carbon over nitrogen in the digestive system, and

they can be controlled by a more nutritious diet. Livestock will also grow faster when well fed, and thus the CH_4 emissions per unit production are reduced from both sides of the ratio (Herrero *et al.*, 2009, 2010). For dairy cattle, the conversion of paddy rice to fodder grass production is economically attractive in certain areas; whereas cut-and-carry systems make livestock compatible with forest protection on slopes (Lusiana *et al.*, 2012). The flipside of improved nutrition is an increase in N_2O emissions from the N rich manure produced. On balance, however, intensification of livestock management can reduce emissions per unit livestock product – but an increased share of such products in the diet of a wealthier human population is increasing the human footprint. More radical solutions are to make more insect protein attractive for human consumption (van Huis, 2013).

Reducing CH_4 Emissions by Less inundation of Rice-Fields

Methane emissions from rice agroecosystems depend on the water regime, straw incorporation, and nitrogen fertilizer levels (Wang *et al.*, 2012). Substantial methane emission reduction without negative yield effects is possible by careful timing of inundation periods, which also help in weed control, and dryland conditions (Green, 2013). Not only the water level, however, but also water flow within the field needs to be taken into account in methane reduction strategies (Rizzo *et al.*, 2013).

Wiser Use of Peatlands

As the collapse and subsidence of drained peat interacts with the water management, agricultural use that is compatible with a water table of approximately 30 cm can substantially reduce emissions although maintaining agricultural production. Banning the use of fire in peatland clearing is one of the most cost effective ways to reduce emissions, but a reorientation of agricultural intensification to mineral soils is highly desirable in a mitigation context. Peatland agroforestry options exist (Tata *et al.*, 2013; Mulia *et al.*, 2013) and are worthy of further exploration.

Better Waste Recycling

Waste is a secondary resource. Organic material can be used for its energy content (by direct burning or in a methane digester producing biogas), for its role in protecting the soil during a surface decomposition process, or by incorporation into the soil enhancing soil organic matter formation. There are tradeoffs between these functions. If N-rich biomass is left on the surface, such as clippings from leguminous trees, N_2O emissions can be high (Verchot *et al.*, 2006), but it is an open debate how important aboveground residues are for soil carbon formation relative to root inputs in no-till agricultural systems. If not needed for surface protection, they might be harvested as fodder or for energy content without harm to longer term soil carbon storage. However, the smoke of manure or crop residues used as fuel tends to contain a high particulate matter content, which forms aerosols and has a direct impact on regional climates through particulates in haze, as well as on global climates (Granier *et al.*, 2011; Mahowald *et al.*, 2011).

Increased Carbon Storage in Soils

The third IPCC assessment identified increased soil C storage as the primary option for agriculture to directly contribute to climate change mitigation (Smith *et al.*, 2008). Most of this change was expected to come from widespread adoption of conservation agriculture systems with reduced tillage. There is considerable debate, however, on the interpretation of the data available, especially where the relative distribution of crop roots and soil organic matter is influenced by a change in soil tillage (VandenBygaart and Angers, 2006). Assessment in the top 100 cm of the soil profile may show less effect than an assessment in the top 30 cm, whereas the most impressive changes in soil carbon are obtained in the top 5–10 cm (Stockmann *et al.*, 2013). Soil carbon needs a long-term perspective, with most of current understanding based on the very few long-term experiments that have primarily been used to calibrate the dominant soil carbon models (Powlson *et al.*, 2011). There is evidence, however, of a soil carbon transition curve as a side-effect of agricultural intensification (Minasny *et al.*, 2011; Xu *et al.*, 2011; Stockmann *et al.*, 2013), but with specific attention to incentives, increments might be faster. On mineral soils, however, it requires many years of high organic matter inputs to increase the soil carbon content by 20 tC ha^{-1}. The case for recovery of soil carbon in overgrazed and degraded drylands is sufficiently strong to warrant action, as the areas involved are large (Wang *et al.*, 2011a).

Increased Carbon Storage in Trees in the Agricultural Landscape

Increments in aboveground soil C storage of 20 tC ha^{-1} can be more easily achieved by incorporating trees into farming systems. If in a rotational system, trees are harvested when they reach a 40 tC ha^{-1} stock level, the time-averaged C stock over the rotation length is approximately 20 tC ha^{-1} (Hairiah *et al.*, 2011). Double this amount is quite feasible, and aboveground gains in C stock are thus more easily made than belowground ones. Given the prominence of trees outside forest and trees spread in agricultural landscapes (de Foresta *et al.*, 2013; Zomer *et al.*, 2009), a reassessment of the relative importance of tree versus soil carbon-based strategies from the third IPCC assessment report (Smith *et al.*, 2008) may be needed (Aertsens *et al.*, 2013; Mbow *et al.*, 2014). Trees moreover have many direct impacts on local climates, including their roles as windbreaks and as providers of topsoil moisture during periods of water stress (Bayala *et al.*, 2008). They are a key element in the bypass loop from human activity to climatic conditions influencing people (**Figure 1**), outside of the formal reach of 'mitigation' as understood in UNFCCC, but well aligned with local knowledge and perceptions (van Noordwijk *et al.*, 2011; van Noordwijk *et al.*, 2014c). Many trees additionally produce food and nonfood products, which have income and livelihood benefits for the local population (Leakey, 2012; Mbow *et al.*, 2014).

Indirect Emissions, Emission Displacement, and Macrosolutions

As indicated, summaries such as Vermeulen *et al.* (2012) see land use change and the conversion of land to agriculture as a large component of current agricultural emissions. This implies that obtaining higher yields from existing agricultural lands, even if it increases area-based emissions, may be an overall mitigation strategy (Lambin, 2012). If instead of a global a national perspective is taken, however, the issue of indirect emissions is missing from the current accounting systems. If, however, indirect emissions are introduced into product-based footprint calculations, the outcome is controversial.

Historically, many countries have been able to transit out of an economic dependence on primary agricultural production, with positive consequences for their forest area and tree cover. Part of the forest recovery is the consequence of the pull of rural populations toward urban and industrial areas elsewhere. Part is also due to the push for labor-extensive, profitable tree production systems, once the opportunities for essentially free harvest from natural forests are gone. However, as analyzed by Meyfroidt and Lambin (2009, 2011), countries that reported an increase in forest, such as Vietnam, have generally achieved this by increasing their external footprint. On an area basis, half the gain in forest cover is offset by expansion elsewhere.

Where indirect land use change emissions are included in a product-based footprint, all producers of the same crop are supposed to have a joint responsibility on how production is managed. This goes substantially beyond the responsibility of a land manager for the specific conditions under which she/he produces the crop, in the upper or lower part of the management swing potential (Davis *et al.*, 2013). Inclusion of indirect land use change in the rules thus has consequences for the possible incentive systems to achieve agricultural mitigation by reducing the footprint of the marketed products and reducing the net emissions from the total agricultural area while increasing total yields.

Carbon Markets and Other Experiments with Micro-Incentive Systems

In response to consumer concerns, the food and agricultural processing industry has learned to respond to environmental concerns, including those on carbon footprints. Where the swing potential is large, as in the case of palm oil, the part of the food industry that targets markets with critical consumers (especially in European markets), it is keen to get associated with the upper segment of the swing potential, by creating voluntary standards of good performance. The Round Table on Sustainable Palm Oil (RSPO) has been pioneering this approach, but similar initiatives exist on other commodities. It is unclear, however, at what scale and time frame such efforts contribute to global mitigation, as substantial emission displacement can occur through a switch of the production in the lower segment of the swing potential to markets that are not accountable and not interested (e.g., palm oil export to other Asian countries).

A major challenge in incentive systems, such as a carbon market, is whether it can provide investment in a shift to other development trajectories that can become financially sustainable on their own, or whether it only implies offsetting opportunity costs and will have to be continued, as a form of payment for environmental services (PES) for an indefinite period of time (van Noordwijk *et al.*, 2012). The EU AgriEnvironment scheme, as one of the largest such efforts to support public policies in the rural landscape, has tried to introduce more conditionality of payment against environmental performance, including a requirement of increase in soil C content, but there are strong countervailing forces. There are many issues with economic incentives for agricultural mitigation (**Table 2**), operating in different policy domains, and with different challenges of achieving additionality (environmental performance above baseline) and avoiding leakage (negative environmental effects outside the primary accountability domain).

Closing Remarks

There is a probability that current efforts to achieve mitigation have actually made things worse. Franks and Hadingham (2012) gave examples how a farm-focused effort at emission reduction in selected countries can lead to increases rather than decreases of global emissions. Henders and Ostwald (2012) in their overview of leakage in a forest context, also included relations with agricultural land use. Two decades of international climate negotiations to effectively implement the agreed framework convention, dealing with the additionality and leakage issues, have made very little progress. There may be some progress in bridging current debates on REDD + and Nationally Appropriate Mitigation Actions in developing countries, but we are far from a Reducing Emissions from All Land Uses ideal.

The dominant focus of the UNFCCC framing of the climate problem on GHG emissions is under scrutiny, with consequences for the way mitigation is perceived, especially in the land use sector. Firstly, there is growing recognition of the Faustian choice that derives from the net effect of air pollution on a global cooling, masking 50% of the committed GHG warming from the Industrial Revolution (Unger, 2012). Aligned with that view, is the enhanced visibility of global climate change after industrial sulfur dioxide emissions were reduced. Aggressive reduction of air pollutants, including fine particulate matter from biomass burning that causes haze, would increase climate warming (Jacobson, 2004; Lamarque *et al.*, 2010). Within the air pollutants, however, methane through its effect on ozone decay (Fiore *et al.*, 2008), is a candidate for selective reductions in warming air pollutants, which may provide a way to mitigate near-term warming by complete pollution control until CO_2 reductions take effect (Unger, 2012). Worldwide implementation of current CH_4 emission control technologies in waste management, agriculture, and the extraction and transport of fossil fuels by 2030 would lead to a reduction in anthropogenic CH_4 emissions of 24% (relative to 2010 levels) and decrease the global mean warming by an estimated central range of 0.2–0.4 °C relative to a business-as-usual scenario (Unger, 2012).

Table 2 Incentive systems for achieving agricultural mitigation

Accounting principle	*Economic incentives to mitigate net greenhouse gas emissions from agriculture*	*Additionality*	*Leakage*
Area-based (Annex-I countries)	National (or European Union-level) emission reduction commitments translate into incentive systems to reduce agricultural emissions, and into formal carbon markets that might in future allow agricultural emission reduction credits to be exchanged for fossil fuel emission permits; the carbon market in Europe is currently restricted to fossil-fuel emission rights	Currently, agricultural mitigation is a cobenefit from other actions to make agricultural landscapes multifunctional and make agriculture sustainable	As international agreements do not yet include the land use sector, leakage is not a big risk
Area-based (outside of Annex-I countries)	Voluntary action to reduce emissions, often project-based; naming and shaming of export-oriented agriculture with high emissions leads to shifts in behavior; in North America, outside of Kyoto protocol and its compliance rules, carbon markets have emerged that support a shift to conservation agriculture for its C storage effects	A/R-CDM rules for additionality have been simplified for small-scale projects, but still are not widely used; voluntary carbon market standards such as VCS support well-intentioned action, limited in scope and reach	Leakage risk in restoration is small; leakage has been the primary challenge for protection of C stocks in REDD+, and require accountability at national scale
Product-based (footprint and efficiency criteria)	Consumer choice for products with lower footprint, often supported by forms of ecocertification and industry self-regulation, allows some linkage between consumers and producers, but is challenged by indirect emission concepts as it can cherry-pick the cleanest part of production systems without impact on the sector as a whole	If footprints calculations would cover all activities and value chains, a real reduction in environmental impacts per capita may be expected	Indirect land use change represents 'leakage,' but is controversial in its application

Abbreviations: A/R-CDM, afforestation and reforestation as part of the clean development mechanism; REDD+, efforts to reduce emissions from deforestation and forest degradation; VCS, voluntary carbon schemes.

Second, non-GHG influences of land cover and land use on rainfall, windspeed, maximum daily temperature, and other aspects of climate fall technically outside of the remit of the mitigation agenda. However, they may well have been underestimated in the public and policy discourse on climate modification that became overly carbon-centric.

Third, and sadly, public discourse remains interested in oxygen supply by plants, rather than the carbon balance and GHG effects, even though this is a nonissue in any place other than a space capsule (van Noordwijk and Lusiana, 2013).

Franks and Hadingham (2012) concluded that auditing methodology of the Kyoto Protocol is at fault. They suggest that a consumption, rather than a territorial/production, approach could be more effective, especially if it includes GHG emissions that are a consequence of farmer's decisions including overseas land use change. However, current life-cycle accounting is often still partial; allowing the term waste to be used. Waste is a wasteful concept, without specifying how and where it returns to global cycles of nutrients (and other elements), and links to energy/entropy flows. The current deficiency in recycling/reuse has multiple rationales, but it partly represents major progress in public health in breaking the life cycle of human parasites and causal agents of diseases. Closing the urban–rural loop in food production, consumption, and waste management would represent real and lasting agricultural mitigation.

Glossary

Disease management Methods to prevent and control diseases and their effects on crops.
Emerging disease A disease that is increasing in incidence, host or geographical range, or virulence and/or has been newly discovered.
Environment The biotic and abiotic elements surrounding an object or organism.
Epidemic Increased occurrence of disease in a population.
Host A living organism that is invaded or infected by a parasite and from which the parasite obtains partial or total nourishment.
Incidence The number of plants affected by a disease within a population, commonly expressed as a percentage.
Inoculum Pathogen or its parts that can cause infection.
Pathogen An organism capable of causing disease in a host.
Resistance The inherent ability of an organism to prevent or reduce the effects of a damaging agent (antonym: susceptibility).
Severity Measure of damage in a plant tissue area caused by a disease.
Symptom Internal or external manifestation of disease on a host.
Vector A living organism capable of transmitting a pathogen from one plant to another and spreading disease.

Plant Diseases and Weather

Plant disease can be defined as any disturbance of a plant that interferes with its normal growth and development, economic value, or esthetic quality and leads to development of symptoms (Shurtleff and Averre, 1997). Plant disease is addressed using a narrower definition – disease as a consequence of infections caused by pathogens (Buczacki and Harris, 1981). Weather plays a key role in disease development and pathogen dispersal from one plant to another, facilitating or limiting new outbreaks and generating epidemics. Under climate change scenarios, changes are expected in epidemic rates and geographical distributions, emerging and reemerging diseases, and overall alterations in economic, social, ecological, and agricultural dynamics driven by plant diseases.

Humanity has suffered disastrous effects of plant disease epidemics. Thus, to understand the biological and environmental factors that contribute to epidemics is crucial, and such knowledge should help one to design the principles, practices, and, strategies for effective plant disease management (Campbell and Madden, 1990).

Plant Diseases and Their History

Historically, the emergence of plant pathology as a science began in the eighteenth century. The use of words now common in plant pathology, like 'plant parasite' or 'epidemic,' originated at that time (Rapilly, 2001), as well as the introduction of the concept of 'a living agent causing human, animal, or plant diseases' by Richard Bradley in 1721 (Santer, 2009). This fundamental idea in modern medicine, veterinary science, and plant pathology was denied by the scientific community at the time. The effects of pathogens on crops have been a commonplace for human society since the invention and practice of agriculture. Porta Puglia and Vannacci (2012) discussed how plant diseases were recorded early in human history by authors like Homer, along with reference to plant diseases in the Old Testament.

The Greek philosophers Democritus and Theophrastus identified some plant diseases and speculated about the causes and origins of those phenomena. Romans were also aware of the consequences of crop pathogens, and authors such as Lucretius, Pliny, and Columella, among others, recorded some cases. As an example of the awareness of plant pathogens in Roman times, a religious ceremony was created in order to appease the anger of Rubigo, a deity that was believed to cause rust diseases on small grains (Porta Puglia and Vannacci, 2012).

The examples of plant diseases described in ancient times are not unique to Europe or the Middle East. In AD 400–800, Mayans experienced a decline in corn production, probably as a consequence of plant diseases. Before the Spanish Conquest of the Americas, Mexican indigenous society identified *Chauiztli* or *Chahuixtle*, now known as corn rust. As early as 1590, records of potato late blight were found in Peru and in Colombia, Brazil, and Mexico in the seventeenth century (Nolla and Valiela, 1976). The history of plant diseases started with the beginning of agriculture, and new diseases continue to emerge.

Plant diseases have affected the economy and the development of the culture, as the following examples illustrate. Some of these diseases are still a threat to food security around the world.

Irish potato famine and German famine

Potato late blight, caused by *Phytophthora infestans*, caused yield losses that resulted in massive human migration from

 doi:10.1016/B978-0-444-52512-3.00004-8

Europe to America. This disease was favored by cool, wet weather (Campbell and Madden, 1990). Potato was the main staple at the time in Ireland and this disease devastated the crop between 1845 and 1849, destroying up to 80% of production. Approximately one million people left Ireland for the United States and Canada in one of the largest human migrations in modern times (Ristaino, 2002), and approximately 2 million people died of starvation (Rossman, 2008). Some neighboring countries – Belgium, Germany, Holland, France, Switzerland, Italy, England, and Scotland (Ristaino, 2002) – suffered the effect of the epidemic, but consequences for them were less dramatic because they depended less on potato as a primary food (Porta Puglia and Vannacci, 2012).

A second case of famine produced by *P. infestans* occurred during 1916–17 in Germany. Copper, commonly used in late blight management, was in short supply because of its use during World War I. As a consequence, disease management was less effective, reducing the potato supply for the German people. It is speculated that reduced food availability affected army morale and could have influenced the outcome of the war (Mitzubuti and Fry, 2006).

American chestnut and its decline in the United States

The American chestnut, once a major forest species in the eastern United States, was reduced to a minor forest component by the fungus *Cryphonectria parasitica*, the causal agent of the disease chestnut blight (Anderson *et al*., 2004). The North American distribution of American chestnut was from the states of Georgia and Mississippi to Michigan and Maine, including some areas in Ontario, Canada (Agrios, 2005; Campbell and Madden, 1990). In a period of 50 years starting in 1904, when the disease was first reported in New York, native American chestnut stands were practically wiped out after the introduction of the pathogen from Japan during the late nineteenth century. This loss has been called by McKeen in 1995 as "the greatest single catastrophe in the annals of forest history," given not only the loss of chestnuts but also the resulting ecological impacts. These forests were the most important source of hardwood for many purposes (furniture, fences, poles, and railroad ties) and were also a source of tannins for the leather industry (Campbell and Madden, 1990). Another consequence of the loss of American chestnuts was the replacement of natural tannins produced by trees with synthetic agents in the leather industry. The timber loss was estimated conservatively to be 30 billion board ft (Campbell and Madden, 1990).

Coffee rust and its impact on former Ceylon's economy during the nineteenth century

During the 1870s, Ceylon, a former British colony known today as Sri Lanka, was the largest coffee producer in the world, satisfying the demand for the former British Empire's preferred hot beverage (Campbell and Madden, 1990; Fletcher, 2011). A rust epidemic caused by a fungal pathogen (*Hemileia vastatrix*) was responsible for replacing the once predominant coffee crops in Ceylon with tea plantations. Coffee rust, the most destructive disease of coffee (Agrios, 2005), was reported for the first time in 1861 (Lake Victoria, Kenya) in wild coffee. Then it was reported in Ceylon in 1869, where the disease took 28 years to change the agroecosystem (Staples, 2000). It is commonly suggested that as a consequence of this disease, Britain became a tea-drinking society (Ainswort, 1969), although other social and economic factors probably also played a role in this transition (Madden, 2013). What is clear is that coffee production moved to other countries in South and Central America. A new epidemic was then discovered during 1971 in Brazil, and from there the pathogen spread over South and Central America in countries whose economies depend on coffee production (Campbell and Madden, 1990; Staples, 2000). The coffee rust epidemic of 2013 threatened the livelihoods of many smallholder farmers in the Americas, amid speculation about the role of climate change.

The great Bengal famine: Brown spot of rice

During 1943 the region of Bengal – today Bangladesh and the state of West Bengal in India – suffered a devastating famine in which 2–3 million people died from starvation (Islam, 2007). Rice in the region was destroyed by brown spot (caused by *Bipolaris oryzae*). The brown spot epidemic and bad management decisions during the crisis by the administrative entities were responsible for the catastrophic famine (Islam, 2007; Padmanabhan, 1973). One of the factors contributing to the development of the epidemic was the unusual weather: heavy rains, prolonged cloudy weather, and warmer temperatures (Padmanabhan, 1973).

Southern corn leaf blight

In 1970 in the United States, the fungus *Bipolaris maydis* caused a Southern corn leaf blight epidemic that generated losses of approximately US$1 billion. That year in February, the disease was found in Florida in corn hybrids, which previously were resistant to *B. maydis*. All infected plants had something in common: they were produced using the gene for Texas cytoplasmic male sterility. This observation was frightening, because nearly 85% of corn in the United States was produced using this breeding technique. By May, the pathogen was well established in the southern part of the United States and weather conditions were extremely favorable to spread of the disease to the north. Tropical storms moved the inoculum from the Gulf of Mexico into the Midwest in July and the weather conditions were perfect for the pathogen to infect and reproduce (Campbell and Madden, 1990). This is a dramatic example of how host population homogeneity, when it includes susceptibility to a particular pathogen species or subpopulation, can have devastating epidemiological and economic consequences. At the time, almost 100% of the corn planted in the Midwest was genetically similar and had the Texas male sterile cytoplasm that was susceptible to the virulent type of the pathogen (Race T) (Rossman, 2008).

Ergot and ergotism: lysergic acid diethylamide and the holy fire

Claviceps purpurea is a fungus that infects rye, producing a structure on grains called a sclerotium, or ergot, that contains large amounts of alkaloids, like lysergic acid diethylamide (LSD). The consumption of bread made with rye flour contaminated with sclerotia generates a variety of symptoms, including fever, hallucinations, and even death depending on the amount of alkaloid ingested. The plant disease, also

called ergot, was first recorded around AD 857 in the Rhine valley, Europe, where thousands of people died. The human disease is known as Ergotism but was colloquially named 'the holy fire' because of the symptoms produced in humans. A second epidemic occurred in France during AD 1039. The disease was also present from the eleventh to the thirteenth centuries in France and Germany and in Russia during 1722, potentially contributing to the defeat of Peter the Great of Russia. In the United States it is believed that ergot caused symptoms in some people that influenced the witchcraft accusations in Salem, Massachusetts in 1692. Recent times have also witnessed ergot epidemics, such as during 1951 in the south of France, causing 200 cases of severe illness, 32 cases of insanity, and 4 deaths. Cases of the disease were also found in Ethiopia in 1977–78 (Campbell and Madden, 1990).

Current Case Studies

Plant diseases continue to threaten food security and natural plant systems. These current examples of epidemics illustrate the importance of pathogens and plant diseases and the need for continued development of improved management strategies, including adaptation to climate change.

Other recent Phytophthora epidemics

Phytophthora species cause a wide range of symptoms and in some cases are difficult to diagnose, allowing the pathogen to remain incognito (Frankel and Hansen, 2011). *Phytophthora cinnamomi* can cause disease in more than 1000 species of plants and has damaged Australian natural plant communities. *Phytophthora ramorum* is the best studied, monitored, and managed forest pathogen species in the United States because of its important impact on trees and other plant species (Frankel and Hansen, 2011; Garbelotto and Pautasso, 2011). This pathogen is the causal agent of diseases such as sudden oak death and ramorum blight of coast live oak and tanoak in native forests, especially in the western US states California and Oregon. Other tree species in European and American forests are also affected (Grunwald *et al.*, 2009). The management of this disease is complex and needs to address three levels: the individual plants affected, the forest, and regional/international management and policies (Rizzo *et al.*, 2005).

Phytophthora infestans caused a pandemic during 2009 and 2010 in the Northeastern United States. A large proportion of organic tomato growers, home gardeners, and some commercial producers lost their production. Losses were up to 100% in some regions. The outbreak of the disease occurred mid- to late-June over most of the Northeastern United States (Fry *et al.*, 2013). This is a very interesting case because of the pathway of epidemic spread. Initially, it followed the shipping network among different retailers. Plants were sold in shops from Pennsylvania to Maine. By mid-August all counties in New York reported the presence of the disease. The weather in the region was relatively favorable for the disease, allowing plants infected in home gardens to sporulate, disperse, and infect neighboring plants, generating the epidemic (Fry *et al.*, 2013). This is an example of how an epidemic can develop in a short period of time, with important economic consequences.

Cassava mosaic virus

Cassava (also called yucca) is the sixth most important food crop worldwide and the third most important source of calories in the tropics. More than 800 million people depend on this plant – tubers and sometimes leaves – as their main staple (Burns *et al.*, 2010). Cassava is the principal source of carbohydrates in several of the poorest countries in Sub-Saharan Africa. *Cassava mosaic virus* (CMV) is a key pathogen affecting cassava in Africa, Sri Lanka, and India (Otim-Nape and Thresh, 2006) and can be transmitted both by whitefly (*Bemisia tabaci*) and through vegetative propagation (Fargette *et al.*, 2006).

CMV was first reported in 1894 in Tanzania (Fargette *et al.*, 2006). The first epidemic during the 1920s in East and West Africa coincided with the increase of cassava production in Africa. The second and third epidemics occurred in the 1930s in Cape Green and Nigeria and during the 1940s in Madagascar, with a more recent epidemic in Uganda in the 1990s (Otim-Nape and Thresh, 2006).

In 1990, a famine in Uganda was caused by a shortage of cassava due to an outbreak of CMV. This epidemic spread to neighboring countries (Kenya, Tanzania, Burundi, and Rwanda) acquiring the status of pandemic and threatening other cassava-producing regions. Cassava production is mainly on a small scale and the virus remains prevalent in many areas. There was evidence of African crop losses ranging from 15% to 24% (Otim-Nape and Thresh, 2006).

Consequences of this epidemic were a decline in cassava production, a decrease in planted area, a rise in prices, and also increased theft of cassava as its price increases. Affected families relied heavily on cassava as a subsistence crop and suffered a decrease in their income. Some positive consequences, like allocation of funds for cassava rehabilitation projects and increased use of resistant varieties, have been observed during and after the epidemic. Recent analyses of CMV impacts in Africa – nowadays confirmed as involving at least two geminiviruses (*African cassava mosaic virus* (ACMV) and *East African cassava mosaic virus* (EACMV)) (Fargette *et al.*, 2006) – indicated losses of 47% of production, generating local famines (Burns *et al.*, 2010).

Canola diseases

Important recent epidemics in canola of Sclerotinia stem rot, caused by *Sclerotinia sclerotiorum*, occurred in England in 1991 and in 2007. In 2007, 5.7% of plants were affected by the disease, generating the worst epidemic since 1991 (Gladders *et al.*, 2008). It has been suggested that weather factors and variation in inoculum were main factors in the development of the epidemic. As a consequence, higher production of inoculum in the coming years was predicted (Gladders *et al.*, 2008). During 1991, disease levels were very high with incidence of 46% and an average of 5.5% of plants affected. Weather factors were conducive for the disease in early May and early June (Gladders *et al.*, 1993).

Wheat stem rust

Wheat stem rust, caused by *Puccinia graminis* f.sp. *tritici* (**Figure 1**), had been effectively managed in many parts of the

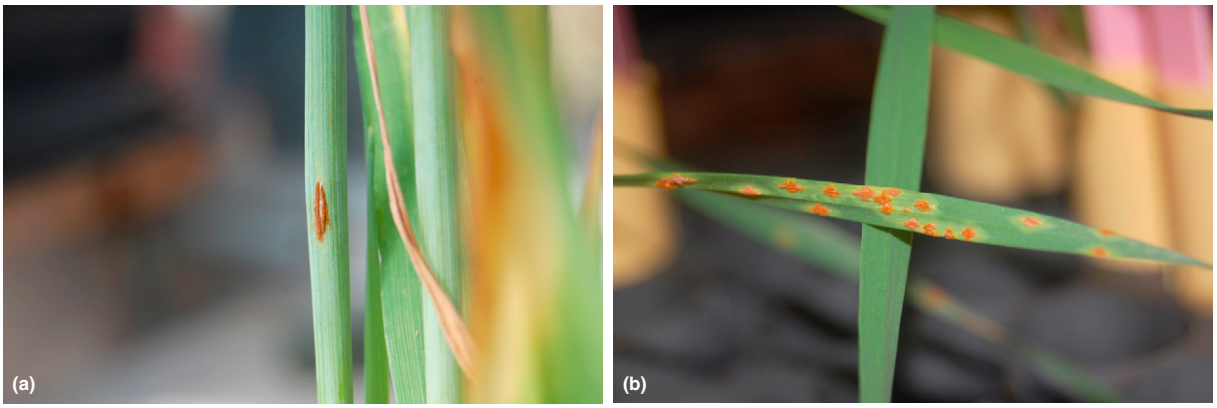

Figure 1 Symptoms (pustules) of wheat stem rust, caused by the fungus *Puccinia graminis* f.sp. *tritici*, on a wheat stem (a) and leaf (b). Photo by John Fredy Hernandez Nopsa.

world using genetic disease resistance. Ug99, a new pathogen race that can overcome common forms of resistance, had the capacity to cause disease in approximately 90% of the wheat population worldwide (Ayliffe *et al.*, 2008; Singh *et al.*, 2011). Given that wheat is the second-largest small grain crop worldwide (FAO, 2013) and that it provides approximately 55% of the carbohydrates and 20% of humankind's calories (Joshi *et al.*, 2011), new pathogens are important challenges to food security. Current management efforts include development of new resistant cultivars, chemical control, and the development and improvement of epidemiological tools that help farmers, producers, and scientists to predict when an epidemic will occur.

General Taxonomic Groups of Pathogens

Plant pathogens cause a wide range of diseases in plants that affect the quantity, quality, and safety of food products; restrict agro-based industries; and affect the biology of ecosystems. Taxa that have evolved mechanisms to parasitize plants include fungi, bacteria, viruses, nematodes, parasitic plants, viroids, protozoans, and algae. Pathogens fall on a continuous scale from facultative saprophytes (that can survive in soil and plant debris) at one end to obligate pathogens (that cannot survive without a host) at the other. They enter plants via a variety of methods, including direct penetration into the host, through natural wounds and openings, vector feeding, and through seed and other propagation methods. Plant pathology, or phytopathology, is the study of the biology, ecology, and epidemiology of plant diseases, ultimately aiming to identify management tools to limit damages associated with plant diseases. The first step is to understand plant disease etiology.

Fungi

Fungi are an important group of plant pathogens that cause a high proportion of plant diseases. Organisms in the kingdom Fungi are eukaryotic, comprised of hyphae or yeast cells, and reproduce by sexual or asexual spores (Figure 2) dispersed by rain splash, wind, humans, animals, seed, and soil movement. Fungal plant pathogens are distributed in all major phyla,

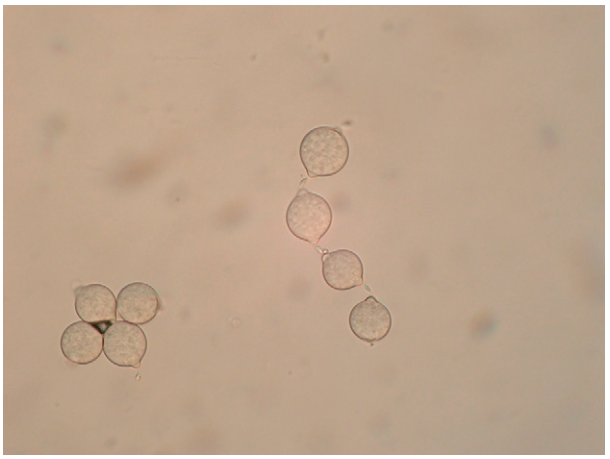

Figure 2 Typical chain of conidia (asexual spores) of the ascomycete *Monilinia vaccinii-corymbosi* that causes mummy berry disease on blueberries. Photo by Sara Thomas-Sharma.

including Ascomycota, Basidiomycota, Zygomycota, Chytridiomycota, and Deuteromycota. Fungi can survive as mycelium in a host or organic material tolerating wide temperature and moisture ranges (Agrios, 2005). They produce an array of spores for dispersal (such as conidia and urediniospores) and also produce sexual and asexual structures for survival (such as chlamydospores, sclerotia, zygospores, and teliospores). Some fungi have complicated life cycles with multiple spore types and different hosts (such as many rust fungi), whereas others have simple life cycles. Fungi can utilize direct penetration (e.g., *Magnaporthe oryze*) or natural openings (stomata and lenticels) and wounds (e.g., *Botrytis cinerea*) to gain access into the host. During the plant parasitic phase of their life cycle, fungi can produce haustoria (feeding organs) inside the host cell to draw nutrients (biotrophic fungi) or produce enzymes that kill host cells ahead of mycelium development (necrotrophic fungi). This results in a variety of symptoms, including leaf spots, blights, rots, wilts, etc. Some fungi also produce toxins that may aid in plant colonization. These mycotoxins can be toxic to humans and animals, such as deoxynivalenol and zearalenone produced by *Fusarium*

graminearum (Figure 3), fumonisins produced by other species of *Fusarium*, ergotoxin produced by *Claviceps* spp., and aflatoxins produced *Aspergillus* spp. Detection and diagnosis of fungal plant pathogens rely on symptomatology, culturing, spore and fruiting body morphology-based identification, and nucleic acid-based detection techniques.

Oomycetes

Colloquially called water molds, oomycetes are classified in the kingdom Chromista and are fungus-like eukaryotic organisms. They have a cell wall composed of cellulose and glucans (unlike chitin in fungi), aseptate hyphae, and produce sexual spores called oospores (resting spores), and asexual spores called zoospores. They are mostly aquatic or soil inhabiting and cause many devastating plant diseases, such as late blight (*P. infestans*); damping-off in seedlings (*Pythium* spp.); downy mildew diseases on many crops, including *Peronospora manshurica* in soybean (Figure 4); and white rust (*Albugo* spp.). As for fungal pathogens, detection and diagnosis of oomycetes rely on symptomatology, characteristics of oospore and sporangia, and nucleic acid-based detection techniques.

Figure 3 Wheat spike showing the typical symptom of Fusarium head blight, a disease caused by the fungus *Fusarium graminearum*. Photo by John Fredy Hernandez Nopsa.

Viruses

Plant viruses have been among the earliest viruses studied, with *Tobacco mosaic virus* (TMV) discovered by Martinus Beijerinck in 1898. Plant pathogenic viruses are parasitic nucleoproteins that vary in size, chemical composition, physical structure, and number of genomic units. They are transmitted in various ways, including by vectors (insects, mites, fungi, nematode, and parasitic plants), vegetative propagation, pollen, seed, and by contact. Movement of viruses within a plant generally occurs via plasmodesmata for between-cell movement and via phloem for long distance transport. Symptoms associated with plant viruses include mosaic patterns, vein clearing, streaking, stunting, and hypo- or hyperplasia. However, plants can also maintain viruses without any obvious symptoms. Detection and diagnosis of plant viruses can be challenging and are conducted using transmission studies, symptomatology, electron microscopy, serological, and nucleic acid-based techniques.

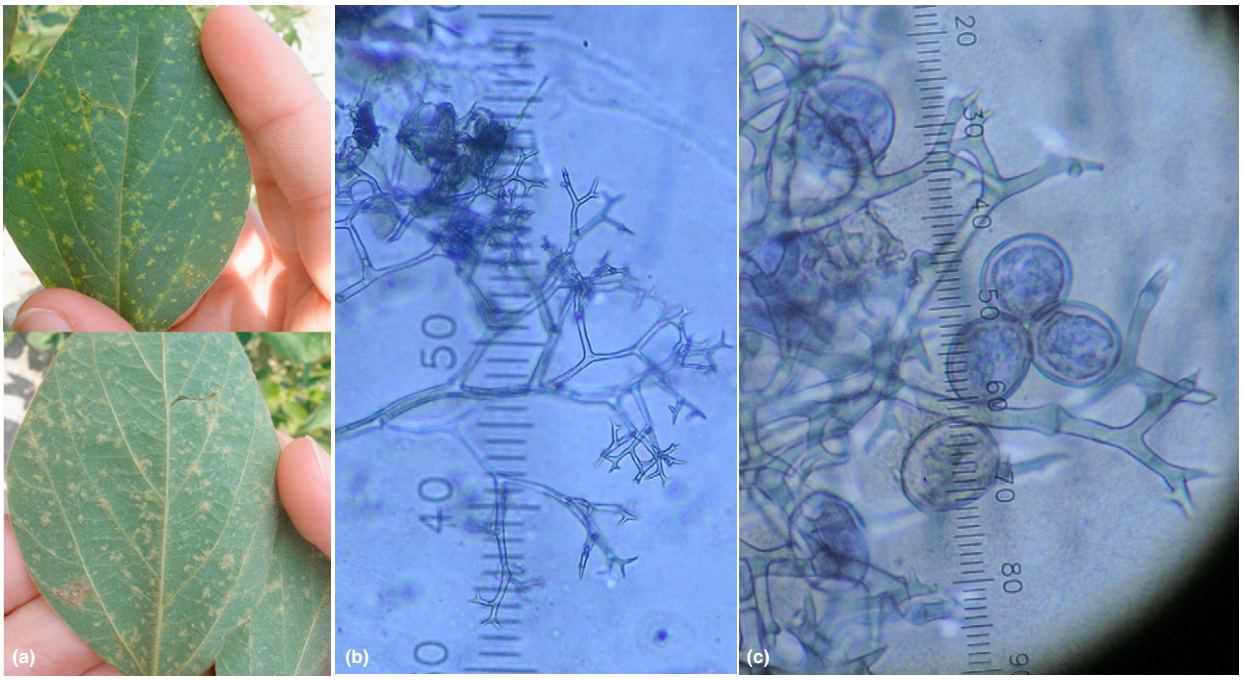

Figure 4 Downy mildew on soybean. (a) Pale green to light yellow spots on the upper surface of soybean leaves and developed grayish mycelia of the oomycete on the lower foliar surface of a soybean leaf; (b, c) determinate growth of sporangiophores showing unattached oval-shaped sporangia (200 × and 500 ×, respectively). Photo by Maria Valeria Avanzato.

Bacteria

Bacteria are prokaryotic microorganisms that belong to kingdom Monera (Prokaryota), with well-known examples including *Agrobacterium tumefaciens*, used routinely for plant transformation, and *Ralstonia solanacearum*, causing wilt diseases in various hosts. Many plant pathogenic bacteria are rod shaped (with an exception of *Streptomyces* spp., which is filamentous), reproduce rapidly by binary fission, can be motile or nonmotile, and are Gram-negative (with some Gram-positive exceptions such as *Clavibacter* spp.). The bacterial cell wall is composed of peptidoglycans, but certain cell wall-less bacteria called Phytoplasmas (class Mollicutes) are also serious pathogens in plants. Plant pathogenic bacteria are found in the soil as saprophytes or on plant surfaces as epiphytes, both of which require natural openings or wounds to gain entry into the host. Inside the plant host, bacteria grow in the apoplast and use secretion systems to release a variety of extracellular virulence factors, such as enzymes, polysaccharides, toxins, and growth regulators, to manipulate host machinery. Many of these processes are population density dependent, allowing bacteria to aggregate before attacking the host. Symptoms associated with bacterial diseases include water soaking, spots, cankers, blights, rots, tumors, wilts, etc. Detection and diagnosis of bacteria is based on symptomatology, culturing and colony morphology, and nucleic acid-based detection techniques.

Nematodes

Nematodes, in the kingdom Animalia, are worm-like in appearance and generally soilborne (with exceptions such as *Aphelenchoides*, a foliar nematode). Although numerous saprophytic nematodes exist in soils, they differ from plant pathogenic nematodes in that the latter have stylets that allow feeding on plants. Nematodes hatch from eggs laid by females either after mating with males or parthenogenetically. The juveniles go through four molts, where in some species the first and second stages do not feed on plants. Soil moisture, aeration, and temperatures greatly affect nematode survival and movement. Plant pathogenic nematodes can be ecto- or endoparasites depending on their feeding location in the root and sedentary or migratory depending on their movement during feeding. Nematode feeding on plants can cause mechanical injury and alter cell physiology because of enzymes in their saliva. Consequent symptoms on plants include yellowing, stunting, hyperplasia at feeding sites such as root knots and root galls, root lesions, etc. Further, nematodes can predispose plants to infection by other soilborne pathogens, often producing wounds that facilitate pathogen entry. Diagnosis of nematode diseases relies on identifying the nematode species based on morphology, by first isolating nematodes using soil isolation techniques, such as Baermann's funnel method, sieving method, and centrifugation or sugar floatation methods (Agrios, 2005). Symptomatology and nucleic acid-based detection techniques are also used.

Others

Other microorganisms such as protozoa, viroids, and algae also cause serious plant diseases (Agrios, 2005). Some such examples include phloem necrosis of coffee (*Phytomonas leptovasorum*), coconut cadang-cadang disease (*Coconut cadang-cadang viroid*), and algal leaf spot of magnolia (*Cephaleuros virescens*). Certain higher plants such as dodder (*Cuscuta* spp.), mistletoe (*Viscum* spp.), and witchweed (*Striga* spp.) are parasitic on plants and can cause significant yield losses in poorly managed crop fields.

How Weather Affects Plant Diseases

Plant diseases result when a susceptible host and infective pathogen interact with each other under favorable environmental conditions. This concept, illustrated by the disease triangle (Figure 5), can be further expanded to incorporate the influence of environment on each biotic component, including the interactions among pathogen, host, pathogen environment, and host environment, and how these interactions change over time (Dixon, 2012).

Thus, environmental factors (in both air and soil) can individually or in combination favor or deter the development of the host, pathogen (and vector), and consequently disease. The prevailing environmental conditions contribute to plant disease variability, affecting disease initiation, development, intensity, and spread. Further, as small changes in these variables can translate into substantial changes in pathosystem dynamics, climate change has the potential to have an important impact on plant disease epidemics.

Temperature

Differences in temperature optima of host, pathogen, and vector play an important role in restricting plant diseases to different geographical areas. Climate change, and the resulting poleward shift of agroclimatic zones, would thus shift regions with temperature optima, potentially increasing the spread of diseases (Coakley *et al.*, 1999). High temperatures can break down resistance in some hosts with heat-sensitive

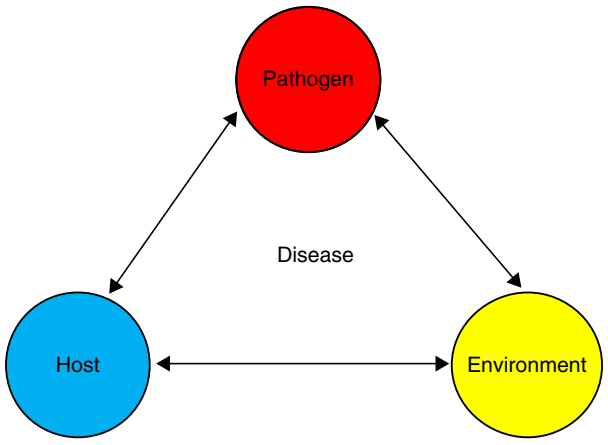

Figure 5 The plant disease triangle. The three necessary causal factors of disease are positioned at the vertices, and the disease occurs with the combination of a conducive environment, a competent pathogen (and in some cases a competent vector), and a susceptible host. Adapted from Francl, L., 2001. The disease triangle: A plant pathological paradigm revisited. The Plant Health Instructor. APSnet. Available at: http://www.apsnet.org/edcenter/instcomm/TeachingArticles/Pages/DiseaseTriangle.aspx (accessed 01.04.13).

resistance genes (Coakley *et al.*, 1999; Garrett *et al.*, 2006). Elevated temperatures can modify the stresses experienced by plants, in turn affecting defense signaling and secondary metabolite pathways that alter plant resistance (Garrett *et al.*, 2006). Temperature changes can also affect pathogen and vector dynamics. Elevated temperatures are known to increase the replication and systemic movement of viruses in plants, alter the accumulation pattern of viruses in mixed infections, and increase virus evolution rates (Canto *et al.*, 2009; Jones and Barbetti, 2012). For bacteria, diseases caused by thermophylic xanthomonads are expected to increase in prominence unlike those caused by thermophobic pseudomonads (Jones and Barbetti, 2012). Similarly, prolonged heat waves are expected to reduce the severity of plant pathogenic bacteria that are temperature sensitive (Jones and Barbetti, 2012). In vectored pathogens, temperature can alter the predominant vector in a region, consequently changing the diseases vectored. For example, in the Andean region of South America, populations of cold-tolerant whiteflies, such as *Trialeurodes vaporariorum*, are displacing the less cold-tolerant *B. tabaci* in higher altitudes, consequently changing the incidence of Potato yellow vein disease (transmitted by *T. vaporariorum*) (Jones and Barbetti, 2012). Higher temperatures are also predicted to increase the reproductive rates of insects. Aphid populations were estimated to increase by five generations per year for a 2 °C increase in global temperatures (Yamamura and Kiritani, 1998). Soil temperatures can also affect the profile and physiology of soilborne pathogens and vectors. For example, the feeding of *Longidorus macrosoma*, a nematode vector of *Raspberry ringspot virus*, was inhibited at high temperatures, reducing virus infections in cucumber (Jones and Barbetti, 2012).

Precipitation

Many plant pathogens, such as nonfastidious bacteria, nematodes, oomycetes, and certain fungi, rely on water for their dispersal. Thus, precipitation patterns serve as drivers of these epidemics and any alteration can change the prevalence and spread of these diseases. In semiarid and arid regions of the mid-latitudes, the incidence of non-vector-borne bacterial diseases that have high moisture requirements are expected to decline (Jones and Barbetti, 2012). Similarly, the Dothistroma needle blight epidemic (caused by the fungus *Mycosphaerella pini*) in North America may be moving north due to higher temperatures and altered rainfall patterns (Woods *et al.*, 2005). In general, there is a correlation between the number of precipitation events per season and the number of infection cycles for pathogens (Agrios, 2005). Vector-borne viral and bacterial diseases can also be affected by changes in precipitation patterns. Long dry seasons, for example, can increase the number of *B. tabaci* generations, consequently increasing the incidence of begomoviruses (Jones and Barbetti, 2012). Similarly, increased soil moisture and temperature in temperate regions may increase epidemics of fungi-transmitted viruses because vector spores will be more easily dispersed. Thus, epidemics of furoviruses and bymoviruses, such as *Soil-borne wheat mosaic virus* and *Wheat spindle streak mosaic virus*, are expected to increase in Canada, Northern USA, Northern Europe, Northeast Asia, and Southern South America (Jones and Barbetti, 2012). However, in rain-fed fields of India and Africa, where reduced rainfall is predicted, the incidence of fungus-vectored diseases like *Peanut clump virus* (PCV) and *Indian peanut clump virus* would be reduced (Jones and Barbetti, 2012). Frequent heavy rainfall can not only wash insect vectors, such as aphids, whiteflies, and thrips, off the plant but also wash bacteria into natural openings and wounds, increasing bacterial diseases. In addition, the success of chemical control strategies could be affected by increased precipitation, because plant protection chemicals can be more easily washed off plant surfaces (Coakley *et al.*, 1999).

Extreme rainfall-related events

Extreme rainfall-related events, such as droughts and floods, can significantly affect plant diseases. Drought and disease can interact in damaging crops, as demonstrated by severe epidemics caused by *Xylella fastidiosa*, *Beet yellows virus*, and *Maize dwarf mosaic virus*, increasing economic losses (Jones and Barbetti, 2012). In other cases, cross-talk between abiotic stress-related pathways and defense signaling can make drought-stressed plants more resistant to disease. Prolonged droughts can have adverse impacts on pathogens and vectors by limiting their population sizes and affecting their dispersal and survival mechanisms. Certain contact-transmitted viruses, such as TMV, that are easily inactivated in aerated soils (rich in antagonistic microflora) can benefit from compact soils in drought-affected areas and waterlogged soils (Jones and Barbetti, 2012). Similarly, nonsaprophytic bacteria like *Xanthomonas citri* subsp. *malvacearum*, causing bacterial blight on cotton, can have greater survival in drought-prone areas. Waterlogged soils (that are not anaerobic) will have higher activity of fungal and nematode pathogens and hence a higher incidence of diseases they cause or vector (Jones and Barbetti, 2012). In contrast, pupal stages of thrips and oviposition of whiteflies are negatively affected by waterlogging, reducing diseases they transmit (Jones and Barbetti, 2012).

Relative humidity

Many fungal pathogens require high relative humidity, and associated surface moisture, for germination and dispersal of their spores. Oomycetes (for most of their life cycle) and bacteria need leaf surface moisture to aid with their movement into natural openings and wounds. Powdery mildews are an exception to this, causing maximum infection in low (50–70%) relative humidity environments (Agrios, 2005). Similarly, flight patterns and multiplication rates of insect vectors can be adversely affected by high humidity. Plants become more succulent and tender under high humidity scenarios, making them more susceptible to contact-transmitted viruses (Jones and Barbetti, 2012).

Wind

Wind drives plant disease epidemics by affecting dispersal of pathogen propagules, increasing drying of host surfaces, and increasing wounding of hosts. Certain spores of fungi (such as urediniospores) and readily airborne insect vectors can be dispersed around the globe by high intensity winds and storms. Periodic increases in wind velocity, consequent to climate change, however, can limit the dispersal of winged aphid vectors and lower the incidence of the diseases they transmit (Jones and Barbetti, 2012). The prevailing wind

direction can also determine the direction of spread of epidemics and disease outbreaks.

CO_2

The CO_2 concentration in the atmosphere affects the rate of photosynthesis, especially in C_3 plants, by altering internal carbon dioxide concentrations (Ziska and Bunce, 1997). Thus, elevated CO_2 improves photosynthesis; increases plant size attributes, such as leaf thickness, area, longevity, and number of leaves; and also increases tillering, stem and root length, and dry weight (Coakley *et al.*, 1999). Such changes alter plant architecture and density, creating more humid microclimates, conducive for many fungal diseases. In addition to this, changes in CO_2 concentrations can alter secondary metabolite pathways in plants, in turn altering the nutritive value of leaves to disease vectors and affecting plant defense signaling. Higher carbon:nitrogen ratios in these plants would also result in slower decomposition of plant litter and greater survival of pathogen resting structures (Coakley *et al.*, 1999). Changes in CO_2 concentration can also affect host–pathogen interactions in different pathosystems. In barley powdery mildew caused by *Blumeria graminis*, an increase in CO_2 results in a reduction in the rate of primary penetration of the host, but increases the growth rate of the pathogen once established (Coakley *et al.*, 1999). Such contrasting results are also seen in virus pathosystems where high CO_2 is predicted to suppress pathogen-induced virus resistance but shown to increase resistance to *Potato virus Y* in tobacco. Similarly, among bacterial pathogens, soft rot of tomato caused by *Pseudomonas marginalis* was inhibited by higher CO_2 concentrations, but incidence of bacterial wilt (*R. solanacearum*) on pepper increased (Jones and Barbetti, 2012). Thus, the effects of CO_2 on plant diseases are pathosystem-specific, making generalizations difficult.

How Climate Change Can Affect Plant Disease

Climate change can directly affect plant diseases by altering the favorability of different environmental conditions for pathogen, host, and vector development. It can also indirectly affect disease development by altering other biological components (such as weed host abundance, vector predation, and symbiont associations) in agricultural and natural ecosystems. The effects of climatic change can also vary from microscopic (leaf wetness and soil temperature) to macroscopic (global temperature, hurricanes, and other extreme weather events) scales. Thus, predicting the overall consequence of climate change on plant disease epidemics requires a thorough understanding of each of these elements and how they interact.

Changes in Pathogen Range

Pathogen range expansions are directly related to host range as well as vector range for vectored pathogens. With climate change, regions in high latitudes and elevations are predicted to become more favorable for many plant species. Resulting host range expansions will provide opportunities for indigenous pathogens to infect new host species and exotic pathogens to move (with their host or vectors) into new geographical areas. Under these new environmental conditions, factors that improve rates of reproduction and survival abilities (ability to oversummer and overwinter) will affect pathogen fitness. For example, predictions for the generalist plant pathogen *P. cinnamomi* in Europe include improved ability to persist under increased temperatures and consequent range expansions (Bergot *et al.*, 2004). In vectored pathogens, pathogen range expansions would also require increases in vector ranges. In temperate countries, insect vectors are expected to have greater survival in warmer winters and faster reproduction with higher summer temperatures. In Europe, aphid-transmitted viral diseases, like potato leaf roll and yellow dwarf in cereals, are predicted to increase under higher temperatures (Jones and Barbetti, 2012). In addition to responses to host and vector range shifts, pathogens can be directly affected by climate change. Generalist viruses, less affected by temperature fluctuations and adapted to wider host ranges, are more likely to expand under climate change scenarios (Jones and Barbetti, 2012). Similarly, fungal, oomycete, and nematode pathogens that depend on water for transport will more likely have reduced expansion in tropical climates with lower predicted precipitation and more frequent droughts. In addition, extreme weather events, like torrential rains, hurricanes, and storms, can transport pathogens across large geographical distances into new regions. A recent expansion of soybean rust (*Phakopsora pachyrhizi*) into North America occurred in November 2004, probably when the spores were introduced by hurricane Ivan.

Changes in Local Disease Severity

Environmental variables can affect disease severity through multiple mechanisms. Temperature may alter the stability of resistance genes, the rates of multiplication of pathogens and vectors, and seed transmission rates of certain viruses (such as *Arabis mosaic virus*). In rice, for example, bacterial blight resistance gene *Xa7* was found to have greater effectiveness against *Xanthomonas oryzae* pv. *oryzae* under increased temperatures (Webb *et al.*, 2010). Low temperature scenarios reduce the effectiveness of plant antiviral mechanisms (such as gene silencing), increasing severity of virus diseases. Further, rates of replication and systemic movement of viruses (such as *Potato virus X* and TMV) in plants are expected to be higher at higher temperatures, resulting in greater disease severity (Jones and Barbetti, 2012). Altered patterns of precipitation can affect dispersal of pathogens as well as the severity of fungus- and nematode-vectored viral diseases. Extreme rainfall events, floods, and droughts can specifically favor or deter diseases depending on the pathosystem. Further, increased rates of reproduction of different pathogens, overlap of areas with different mating types, and higher evolution rates can facilitate the generation of new pathogen strains that are more virulent to crops.

Changes in Pathogen–Vector–Host Associations

Climate change can cause outbreaks of previously uncharacterized disease complexes, reemergence of existing plant

diseases, and alter the relative importance of endemic diseases. In viral diseases, changes in temperature can modify the rates of virus multiplication, accumulation pattern in mixed infections, and transmission efficiency of vectors (Jones and Barbetti, 2012). Taken together with host range expansions, these provide excellent opportunities for the outbreak of new disease complexes. In the Iberian peninsula, where warming is double the global average, diseases such as citrus tristeza, tomato leaf curl, tomato necrosis, tomato mosaic, and cucurbit vein yellowing have emerged in recent years (Canto *et al.*, 2009). Displacement of vectors under different climate change scenarios and their increased activity can change the importance of diseases locally. Examples include the emergence of begomovirus epidemics in the middle latitudes and reduced importance of PCV in the tropics (Jones and Barbetti, 2012). Temperature also affects host–pathogen interactions by allowing host resistance to be overcome by pathogens in some cases. This could be aided by increases in host tissue and morphological and physiological changes in the host (Juroszek and von Tiedemann, 2011).

Changes in Evolutionary Processes

Increases in CO_2 and UV-B radiation have the potential to accelerate evolutionary process in pathogens, allowing them to overcome host resistance more rapidly (Chakraborty *et al.*, 1998, 2000; Garrett *et al.*, 2006). Stages in the life cycle of pathogens, such as production of inoculum, infection, and other stages, are driven by favorable weather conditions. Thus, climate change can influence pathogen evolution. Experiments under elevated CO_2 indicated that the plant pathogen *Golovinomyces cichoracearum* increased in aggressiveness and the host *Arabidopsis thaliana* exhibited different leaf characteristics, making it potentially more susceptible to pathogens. This may represent an acceleration of plant pathogen evolution (Lake and Wade, 2009). The rate of evolution of organisms is influenced by the number of generations per time interval. Temperature has a direct impact on the reproductive process in many pathogens, and in many cases higher temperatures may support faster evolution rates. Longer and warmer seasons may make it possible for pathogens to become more virulent, to become pathogenic in different systems, and to be more aggressive (Garrett *et al.*, 2006). Pathogens may adapt to new climate scenarios and potentially become more virulent. Just as pathogen life history traits influence the rate at which pathogens may overcome host resistance genes (McDonald and Linde, 2002), they will also influence the response of evolutionary rates to climate change.

Changes in Management and Management Efficacy

Biological control agents may become less effective if there is a greater fluctuation in temperature, humidity, rain periods, and other weather conditions under climate change scenarios (Garrett *et al.*, 2006; Juroszek and von Tiedemann, 2011). System-level effects of climate change – such as changes in productive zones, increases or decreases in crop area and diversity, and changes in yield – may produce a direct effect on pesticide use, pesticide activity, and the volumes needed and applied in a given region (Miraglia *et al.*, 2009). An increase in the number of outbreaks could lead to greater use of pesticides, increasing the risk of pest resistance to pesticides. Additionally, faster crop growth may shorten the time between applications, having direct effects on producers, economics, environment, and food safety (Juroszek and von Tiedemann, 2011).

General Predictions for Plant Disease under Climate Change

North American Forests

During the last 50 years, temperatures in Northeastern North America have increased at an estimated rate of 0.25 °C per decade (Dukes *et al.*, 2009). Given that 23 pest species, 8 invasive plant species, and 18 pathogens are predicted to cause negative effects in the region's forests (Dukes *et al.*, 2009), this temperature increase has the potential to cause a number of changes. Precipitation patterns may have influenced the Dothistroma needle blight epidemics in pine in Western Canada (Woods *et al.*, 2005). Forests adapt slowly to environmental change, given the long generation times of trees, a factor making climate change adaptation strategies in forestry more challenging (Boland *et al.*, 2004; Jones and Barbetti, 2012; Sturrock, 2012).

Northern European Agriculture

For high-latitude regions, increases in precipitation are expected during winter and summer seasons. With higher temperatures, an increase in the melting rate of land ice and snow cover is predicted, although snow cover has the potential to increase along with higher temperatures in boreal regions. Driven by higher levels of CO_2 and higher temperatures, increases in plant tissues and leaf surface areas, with associated changes in microclimate conditions (humidity and wetness), may facilitate pathogenic infections and outbreaks of new diseases. For example, warmer temperatures in winter increase the probability of rust overwintering (Pfender and Vollmer, 1999). Many pathogens may experience more conducive overwintering conditions under climate change and so serve as inoculum for the following season. Potato late blight in Finland has been observed earlier in the year over recent decades, although the effects of changes in potato cultivars are confounded with weather effects (Hannukkala *et al.*, 2007).

Tropical Agriculture and Developing Countries

In tropical Africa, precipitation is predicted to increase during the wet season (winter). However, in Central America, a decrease in precipitation is predicted. Pathogens have an advantage over plants because their reproductive cycles are in general faster than plants and their number of generations per time unit is greater, giving them the potential for more rapid adaptation to new climate conditions (Garrett *et al.*, 2006). This pathogen advantage may be even more pronounced in tropical agriculture when long or year-round growing conditions make it possible for continuous pathogen reproduction.

Unfortunately, geographical regions predicted to have significant risks associated with climate change are often regions

with lower abilities to adapt to such risks due to technological and economic resource constraints (Hoffmann, 2011). In developing countries, national program research to help mitigate plant diseases under climate change scenarios – such as development of varieties with stable resistance genes, better vector monitoring and management tools, and improved disease management practices – is often limited. Further, unmonitored range expansions of crops and use of infected seed can result in unanticipated invasions of existing diseases or emergence of new diseases. In both cases, the role of anticipatory research is crucial to alleviate such losses. All the same, developing countries have also shown resilience to climate fluctuations in the past. In the West African Sahel region, rainfall decreases of 25–33% have altered pastoral cultivation and agricultural practices over the years (Adger *et al.*, 2003). Thus, integrating experiential and indigenous knowledge with formal research efforts will be important to manage plant disease under climate change scenarios.

Additional Reading

There are a number of good recent reviews on the subject of climate change and plant disease in addition to those cited above (Chakraborty and Newton, 2011; Eastburn *et al.*, 2011; Gregory *et al.*, 2009; Juroszek and von Tiedemann, 2011; Luck *et al.*, 2011; Newton *et al.*, 2011; Pautasso *et al.*, 2010, 2012; Savary *et al.*, 2011b; Sutherst *et al.*, 2011); this continues to be an active area for synthesis. Reviews have addressed soilborne pathogens, which are generally less studied compared with foliar pathogens but have the potential for particularly strong and potentially surprising responses to climate change (Chakraborty *et al.*, 2012; Garrett *et al.*, 2012; Pritchard, 2011). The effect of climate change on beneficial microbes also merits more attention (Compant *et al.*, 2010). As for forests, plantation production offer challenges because of the long-lived nature of the perennial plant hosts (Ghini *et al.*, 2011).

The inclusion of plant disease and its management in greenhouse gas budgets may support prioritization of management strategies (Carlton *et al.*, 2012; Mahmuti *et al.*, 2009). The complexity of pathogen–host–environment interactions is an important problem for scenario analyses (Garrett *et al.*, 2011; Shaw and Osborne, 2011), and the need for better long-term data sets to validate scenario analyses is an ongoing issue, with some intriguing exceptions (Bearchell *et al.*, 2005; Jeger and Pautasso, 2008). Work is ongoing to develop disease risk assessments at the scales needed for effective prioritization (Savary *et al.*, 2011a; Sparks *et al.*, 2011). The impact of variability in climate patterns, especially extreme events, is an important challenge for scenario analysis for plant disease (Garrett *et al.*, 2013; Rosenzweig *et al.*, 2001; Scherm, 2004; Scherm and van Bruggen, 1994).

Glossary

Carbon footprint The total GHG emissions caused by an activity or product.

Enteric methane (CH_4) emissions Emissions of the greenhouse gas, methane, from the animal's digestive tract that result from microbial activity. Emissions are greater from ruminant species compared to nonruminant species of livestock.

Global warming potential (GWP) The potential for greenhouse gases (GHG) to trap heat in the atmosphere based on its atmospheric lifetime and radiative forcing.

Life cycle assessment (LCA) An evaluation of a given product's environmental impact over its entire production chain.

Production efficiency Minimizing the inputs (e.g., feed and fossil fuels) and undesirable outputs (e.g., greenhouse gas emissions) required to produce a given quantity of animal product (e.g., pork, beef, and milk).

Introduction

Anthropogenic (human-caused) climate change is both impacting animal agricultural systems and influenced by those systems through emissions of greenhouse gases (GHG). Concurrent with global climatic change, global demand for animal agricultural products (e.g., meat, milk, and eggs) is rising with the growing population and increasing per capita incomes in developing nations. The world population is expected to surpass 9 billion by 2050 and demand for meat and dairy products are expected to increase by 58% and 74%, respectively (Garg, 2012). Consequentially, understanding how our animal systems are impacted by and contribute to climate change needs to be discussed within the context of certain growing demand for animal-derived products. Strategies to adapt and mitigate the impacts of these systems on climate change will be an interdisciplinary challenge that will require the cooperation of farmers and ranchers, researchers, extension educators, regulators, and policymakers. Advancements in animal production to address climate change will be a combination of extending current knowledge, innovative research, and effective dissemination of research findings.

The scientific consensus that human activity is contributing to global climatic change among climate scientists is strong (Oreskes, 2004), with several independent attempts to reconstruct global surface temperatures over the last several thousand years leading to the same conclusion; there has been a clear warming trend in the past century, which has occurred at an unprecedented rate (Mann *et al.*, 2008; Marcott *et al.*, 2013). The major cause for the warming trend is increasing concentrations of GHG in the atmosphere, which has been primarily driven by the combustion of fossil fuels since the beginning of the Industrial Revolution. It has been known for more than 100 years that carbon dioxide (CO_2) influences temperature (Arrhenius, 1896), and along with methane (CH_4) and nitrous oxide (N_2O) forms the major GHG emissions that result from animal systems. However, CO_2, CH_4, and N_2O do not all contribute to warming temperatures equally. Each of these gases has a different radiative forcing, or potential to trap heat in the atmosphere, along with a different atmospheric lifetime, which has led to the creation of global warming potentials (GWP) to standardize the impacts each GHG has on temperature (Seinfeld and Pandis, 2006). The Intergovernmental Panel on Climate Change (IPCC) has established GWP as CO_2 equivalents (CO_2e) on a 100 year timescale for CO_2, CH_4, and N_2O as 1, 25, and 298, respectively, meaning CH_4 has a 25 times greater potential and N_2O has a 298 times greater potential to trap heat in the atmosphere than CO_2 on a 100 year time horizon (Solomon *et al.*, 2007). In addition to the concerns about the rapidly changing climate due to human activity, it is also important to note that GHG play an important role in keeping the global average surface temperature of the Earth in a range which is hospitable to life. If the longwave radiation from the Earth's surface was not partially trapped via GHG in the atmosphere, the global average surface temperature would have been −19 °C, rather than 14 °C as it is today (Le Treut *et al.*, 2007).

The impacts of climate change on animal agriculture are expected to be far reaching. Animals will be directly impacted by increased temperatures, which can lead to higher incidence of heat stress resulting in decreased productivity (e.g., decreased milk yield and growth rates), and in periods of prolonged increased temperatures, higher death losses occur (Mader *et al.*, 2009; St-Pierre *et al.*, 2003). Beyond the direct physiologic impacts on animals, climate change will likely impact animal feed crop quality and yield, commodity prices, disease and pest prevalence and distribution, and lead to a higher incidence of extreme weather events (e.g., floods and heat waves) (Craine *et al.*, 2010; Walthall, 2012; Wheeler and Reynolds, 2012). For the purpose of this article, adaptation of animal systems to climate change will not be discussed, but rather the sources of GHG emissions and GHG emission mitigation opportunities will be explored. However, as climate change and variability impact animal productivity, GHG mitigation techniques discussed in later sections of this article will be related in part to the adaptation of animal systems to climate change.

 doi:10.1016/B978-0-444-52512-3.00006-1

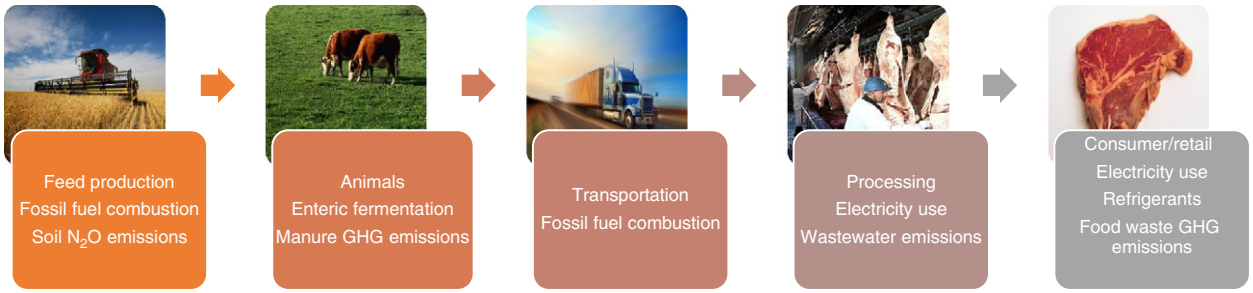

Figure 1 Example of the phases of production and greenhouse gases (GHG) emission sources that would be accounted for in an Life Cycle Assessment (LCA) of beef's GHG emissions or carbon footprint. Methodologies and sources considered often vary from industry to industry and analysis to analysis, which can lead to challenges when attempting to compare across LCA.

Sources of Greenhouse Gas Emissions from Animal Systems

Sources of GHG emissions from animal agriculture systems can be broken down as either direct or indirect GHG emissions. Direct GHG emissions are those that occur directly from the animals (i.e., enteric CH_4 emissions from ruminants) and its waste (GHG emissions emitted from manure). Indirect GHG emissions can be defined as those that occur from processes and activities that are ancillary, but essential for the production of animal products. Indirect sources include on-farm activities (e.g., GHG emissions from farm equipment and fertilizer application) and GHG emissions associated with activities both pre- and postfarm gate (e.g., GHG emissions associated with the production of purchased feedstuffs and transportation of animal products). For the discussion of indirect GHG emission sources, the term prefarm gate will refer to all CO_2e emissions resulting from activities before the animal product (i.e., fresh raw milk, eggs, live cattle, sheep, pigs, and poultry) leaves the site of production (i.e., the farm, ranch, feedlot, etc.) bound to a processing facility. Postfarm gate will refer to CO_2e emissions resulting from activities after the animal product has left the site of production.

An accounting system that considers direct and indirect emissions is consistent with Life Cycle Assessments (LCA) that account for GHG emissions along the entire production chain of a given product. The final inventory for all GHG emissions along the production chain would then be divided by the total product produced to calculate a metric of GHG emissions in CO_2e per unit of product (e.g., CO_2e per kilogram of milk), also referred to as the functional unit (Thoma *et al.*, 2013). However, by analysis, variations in GHG emission inventory infer that the scope and scale of animal agriculture product LCA are not homogeneous. Therefore, comparisons across LCA can at times lead to inappropriate comparisons and conclusions if methodological differences are ignored. Some LCA do not consider the entire product chain, but rather part of the chain (e.g., the GHG emission to the farm gate, which would not include processing, transportation, retail, etc.). Additionally, an LCA may be global, national, or subnational (i.e., a US state) in its scale, which makes extrapolating conclusions from an LCA at one scale to another inappropriate (Pitesky *et al.*, 2009), which is due to the disparate management strategies, climates, animal types, feedstuffs, etc. used in different regions around the world (Place and Mitloehner, 2012). See **Figure 1** for a beef industry example of what processes and segments of the animal agriculture product chain are considered for LCA of GHG emissions.

Direct Sources

Enteric

Enteric CH_4 emissions are one of the major sources of GHG emissions from ruminants (e.g., cattle, goats, and sheep) agriculture systems (Pitesky *et al.*, 2009; Thoma *et al.*, 2013). The production of CH_4 represents a loss of the gross energy (GE) value of the animal's feed, which depending on the diet and level of intake can be a loss of 2–12% of dietary GE for ruminants (Johnson and Ward, 1996). Enteric CH_4 emissions from nonruminant animals do occur from hindgut fermentation processes, but are minor compared to ruminants, with CH_4 emissions typically representing less than 1% of dietary GE for pigs and lower still for poultry (Christensen and Thorbek, 1987; Jørgensen, 2007; Wang and Huang, 2005).

When a ruminant animal consumes feed (e.g., forages and grains), the feed nutrients will undergo fermentation processes resulting in the production of volatile fatty acids (VFA) that are absorbed through the rumen wall and metabolized by the animal, during this process, CO_2 as well as hydrogen (H_2) is produced. Methane emissions do not result directly from the fermentation processes, but rather occur from methanogenesis carried out by methanogenic archaea residing within the rumen. The most prevalent substrates for methanogenesis in the rumen are H_2 and CO_2 (Janssen and Kirs, 2008), with methanogens reducing CO_2 to CH_4 with H_2 summarized in the following equation:

$$CO_2 + 4H_2 \rightarrow CH_4 + 2H_2O$$

Other substrates used in methanogenesis include formate, methanol, and acetate (Russell, 2002). With CO_2 being abundant in the rumen due to the continuous fermentation processes, the pool of H_2 available is one of primary determinants for the total yield of CH_4 from rumen methanogenesis and many mathematical models predict rumen CH_4 production by modeling the rumen H_2 balance (Ellis *et al.*, 2008). For further detailed information, Janssen (2010) conducted an excellent in-depth review of the influence of H_2 on rumen CH_4 formation. The rumen partial pressure of H_2 gas is kept very low through the action of methanogens, which is

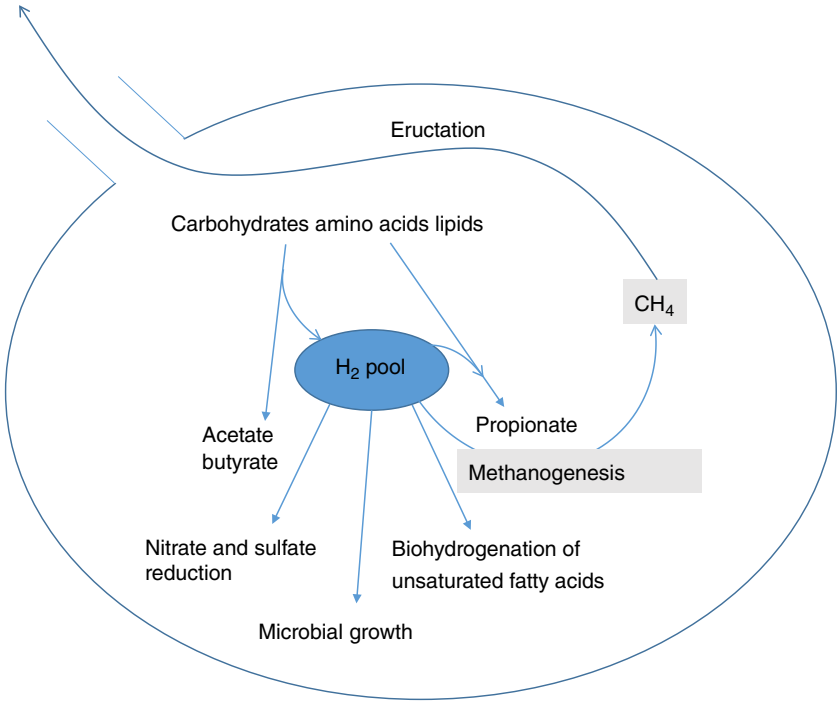

Figure 2 A simplified model of the rumen processes that determine enteric CH_4 emissions from ruminant livestock species.

important as H_2 acts as a feedback inhibitor to fermentation (Immig, 1996). Fermentation pathways that lead to the net production of H_2 include the production of the VFAs acetate and butyrate, while the production of propionate leads to a reduction in H_2 available for methanogenesis (Ellis *et al.*, 2008). The proportions of each of these VFA in relation to total rumen VFA production is greatly determined by diet, with diets higher in fermentable carbohydrates (i.e., starch) yielding more propionate than diets high in fiber (Johnson and Johnson, 1995). Alternative H_2 sinks include the biohydrogenation of unsaturated fatty acids, microbial growth, nitrate reduction, and sulfate reduction (Ellis *et al.*, 2008; Johnson and Johnson, 1995). A simplified model of rumen fermentation and the major H_2 sinks and sources is shown in **Figure 2**.

For animal systems, respiratory CO_2 emissions are usually not counted toward net CO_2e emissions, as it is assumed that the CO_2 released as the result of animal metabolism is equal to the CO_2 used by plants in during photosynthesis, which the animals have consumed (Steinfeld *et al.*, 2006).

Nonenteric

The predominant nonenteric direct GHG emissions source both from ruminant and nonruminant animal agriculture systems (e.g., swine and poultry) is manure (i.e., urine and feces mixed). Manure GHG emissions typically occur from manure storage systems and land-applied manure. The primary GHG emissions from stored manure are CH_4 and N_2O. Fresh manure (e.g., manure on the floor of animal housing areas) results in little or no CH_4 or N_2O emissions (Shaw *et al.*, 2007; Sun *et al.*, 2008). For land-applied manure, N_2O is the major GHG emitted (more discussion in the Sections Indirect Sources and Mitigation). As with respiratory CO_2 emissions from livestock, CO_2 emissions from manure are considered carbon neutral.

Like in the rumen, emissions of CH_4 occur from manure stored in anaerobic or oxygen-free conditions. However, unlike the rumen that has digesta passage rates of upto 20% per hour, manure storage systems often allow fermentation processes to occur undisturbed for weeks or months (Russell, 2002). Consequently, methanogens that can utilize VFAs for methanogenesis can thrive, but in the rumen environment these species are virtually nonexistent due to the high rates of passage and removal of VFAs through the rumen wall (Russell, 2002). Additionally, manure storage systems are typically not kept within a narrow temperature range as in the rumen, and this temperature variability influences the metabolic activity of the microbial populations. Hence, in Northern latitudes, CH_4 emission rates are typically higher during warm summer months than in winter months from manure storage systems (Husted, 1994; Park *et al.*, 2006).

Hydrolysis, fermentation (and acetogenesis), and methanogenesis are the three major steps in CH_4 formation from manure (Gilroyed *et al.*, 2011), which is shown in the simplified equation below:

$$\text{Organic polymers} \overset{\text{Hydrolysis}}{\Longrightarrow} \text{Monomers} \Longrightarrow$$

$$\text{Fermentation/acetogenesisVFAs (acetate)} \overset{\text{Methanogenesis}}{\Longrightarrow} CH_4$$

Organic polymers include carbohydrates, proteins, and lipids. Besides storage conditions and management, the nutrient content of animal manure can influence the CO_2e emission potential of manure. The nutrient content and digestibility of

the animal's diet can impact the carbon (C) and nitrogen (N) availability in the manure and the subsequent CH_4 and N_2O emissions resulting from the manure (Külling *et al.*, 2003).

Nitrous oxide emissions primarily occur from bacterial denitrification processes; however, N_2O emissions also occur from nitrifying bacteria and ammonia oxidizing bacteria (Bremner, 1997). The denitrification process reduces nitrate (NO_3^-) to dinitrogen gas (N_2), which is environmentally benign and composes 78% of the Earth's atmosphere. One of the intermediate products of the pathway is N_2O, hence emissions of N_2O can result from denitrification. Most of the N in fresh manure is in the form of organic N (in a carbon-containing compound, like amino acids) or ammonium (NH_4^+). Thus, very little NO_3^- is present for denitrification. However, if microbial nitrification processes occur, which require aerobic conditions to oxidize NH_4^+ to NO_3^-, the potential for N_2O emissions from the manure will greatly increase. Often, manure storage conditions do not allow for significant enough oxygen presence for nitrification to occur. Such storage systems include anaerobic lagoons and anaerobic digesters, and consequently N_2O emissions from these systems are typically low (Chadwick *et al.*, 2011). However, solid manure storage systems and compost bedded pack systems where manure is used as a bedding source for animals and is periodically aerated can allow for the necessary nitrification and denitrification microbial processes to occur that result in N_2O emissions (Rotz, 2004).

For extensive animal systems (i.e., where animals are primarily housed outdoors) manure is unmanaged and distributed where animals defecate and urinate in the pasture or rangeland. Emission factors for N_2O emissions in g of N_2O–N per kilogram of N excreted from urine and dung patches are often higher than manure spread on croplands for fertilizer due to the higher N concentration in the patches, which encourages N_2O emissions (Mosier *et al.*, 1998). Additionally, N_2O emission potential per unit of N excreted is higher for urine patches compared with feces patches, as most N in urine is excreted as urea (vs. organic N in feces), which is typically rapidly hydrolyzed to NH_4^+ and then available to undergo nitrification–denitrification processes (Oenema *et al.*, 1997).

Indirect Sources

Prefarm gate

Indirect prefarm gate emissions include GHG emissions released as a result of feed production for animals (e.g., N_2O emissions from cropland soils and CO_2 emissions from fossil fuel combustion in farm equipment) and on-farm electricity use. Crop production that is destined for animal consumption is typically fertilized either with animal manure or synthetic fertilizer. Nitrous oxide emissions will occur from soil in cropland from the same microbial processes as previously discussed. In addition to the availability and form of N in the soil, N_2O emissions are influenced by the amount of soil C, soil moisture conditions, pH, and temperature (Smith *et al.*, 1998). Emissions of N_2O will be higher with increasing soil C availability, water content, temperature, and pH (Bouwman, 1996).

Methane emissions from soil used for livestock crop production are virtually nonexistent in well drained soils, and CH_4 uptake by soil can occur after tillage (Omonode *et al.*, 2007). Soil CO_2 emissions can occur during the tillage of soil as a result of aerobic decomposition of organic matter; however, plants typically assimilate more C through photosynthesis than C is released from plant and soil respiration processes (Chianese *et al.*, 2009). In assessments of animal system GHG emissions, long-term C balances of croplands are assumed to be zero as the C assimilated by plants or added to the system (e.g., C from manure) will be equal to the C leaving the cropland in the form of feed biomass and CO_2e emissions (Rotz *et al.*, 2010). However, if previously tilled cropland is shifted into permanent grasslands, there can be a net reduction in CO_2e emissions from an animal system due to C sequestration, as long as the grassland is not tilled in the future (Rotz *et al.*, 2009).

Indirect CO_2 emissions occur from fossil fuel combustion in farm equipment, and from electricity generation in power plants that burn fossil fuels, such as coal. Although fossil fuel combustion is not a large prefarm gate emission source for animal systems, the total contribution of these sources to total CO_2e emissions per unit of product depends on the animal agriculture sector considered. For example, a low input grass finished beef system would likely have a lower proportion of its total CO_2e emissions per unit of product originating from fossil fuel use than an intensively managed dairy farm, where cattle are housed in mechanically ventilated barns and are milked twice per day by a milking system using energy off the electricity grid. Furthermore, the contribution of indirect prefarm gate emissions can vary within a sector of animal agriculture based on the management systems used and the geographic location of the farm, which influences climate and the crops that can be grown. Rotz *et al.* (2010) used the DairyGHG model to conduct a partial LCA (to the farm gate) of five simulated US dairies in Pennsylvania and California of different herd sizes (ranging from 60 to 2000 cows) and management strategies (grazing, confined, and drylot). Fuel use on-farm for tractors and other farm equipments ranged from 5.8% to 9.8% of the net CO_2e emissions from the simulated dairy farms. Secondary CO_2e emissions were also considered, which included the GHG emissions from the production of fuel, electricity, fertilizer, machinery, pesticide, and plastics used for feed production, for managing the animals, and manure management. The secondary emissions were found to be 18.9–25% of net CO_2e emissions of the five simulated dairies to the farm gate, which may be higher than some estimates, as the authors included CO_2 sequestration from cropland (Rotz *et al.*, 2010). The simulated 60 cow grazing dairy in Pennsylvania had a lower proportion of its total CO_2e emissions per kilogram of energy-corrected milk coming from on-farm fossil fuels and secondary sources compared with the other systems, which would be expected due to the lower inputs (e.g., less machinery use, electricity use, etc.) of the system (Rotz *et al.*, 2010).

Postfarm gate

The emissions that occur postfarm gate include emissions from fossil fuel burning during transportation, refrigeration of products (leakage of refrigerants that have high GWPs), and

energy usage during processing and for food preparation at retail, restaurants, and in consumer homes. Although there is often a perception that transportation is a large part of the carbon footprint of food (i.e., the total CO_2e emissions associated with the food product) and purchasing local food is prescribed as a solution (e.g., the locavore movement), the contribution of transportation to the total CO_2e emission per unit of animal product is often quite small (Capper, 2011b). Thoma *et al.* (2013) found that 72% of CO_2e emissions per kilogram of milk produced in the US occurred prefarm gate whereas transportation accounted for 7.7%. Ledgard *et al.* (2011) found 80% of CO_2e emissions per kilogram of lamb meat occurred prefarm gate for New Zealand lamb production, whereas only 5% was attributed to transportation, despite the assumption in the LCA that the lamb was exported to the UK.

The GHG emissions prefarm gate are predominately CH_4 and N_2O emissions, whereas postfarm gate GHG emissions are dominated by CO_2 and refrigerant gas emissions. Leakage of refrigerant gases (mainly hydrofluorocarbons) is a significant source of GHG emissions from the postfarm gate segment of the animal system production chain, as these gases have high GWP that depending on the gas can be several hundred or several thousand times that of the 100 year CO_2 GWP (Solomon *et al.*, 2007). In the past several decades, refrigerant leakage rates have been declining (Calm, 2002); however, supermarket average leakage rates are still estimated to be approximately 25% (EPA, 2009). Additionally, CO_2e emissions result from the production of packaging materials for animal products (e.g., boxes, cartons, and containers) that are used during processing, transportation, and retail.

Food waste at the retail, restaurant, and consumer stages of the supply chain of animal products is another important source of CO_2e emissions postfarm gate. A 1997 USDA Economic Research Service study found that 32% of edible dairy products, 31% of edible eggs, and 16% of edible meats (including poultry and red meats) were wasted from the retail, foodservice, and consumer phases of the food supply chain (Kantor *et al.*, 1997). In the US, food waste composes 20% by weight of municipal solid waste entering landfills where it can be a source of CH_4 emissions (EPA, 2013). In addition to the CO_2e emissions that directly result from food waste in landfills, the embedded or embodied energy of food waste can be substantial. Embodied energy of a given product or service is calculated as the total direct and indirect energy required for its production (Costanza, 1980). Cuellar and Webber (2010) estimated that the embodied energy in wasted food represented approximately 2% of US annual energy consumption in 2007.

Mitigation

Metrics for Mitigation of Greenhouse Gas Emissions from Animal Systems

One faces a paradox of mitigating the CO_2e emissions from human activity, including animal systems while meeting the nutritional and material needs of a growing world population during climatic change and variability. Meeting these challenges will require a nuanced analysis and understanding of the implications of policy changes, and dedicated efforts to make concrete, quantifiable on-the-ground modifications that result in lower global CO_2e emissions and increased carbon sequestration. Critical to these efforts is having the appropriate CO_2e emissions measurement system that takes into account the productivity or usefulness of the activity or industry. To this end, CO_2e emissions per unit of output for animal systems is an appropriate way to assess the impacts of animal systems on climate change while recognizing the nutritional benefit of those systems.

Direct Sources Mitigation Opportunities

Enteric

Mitigation of enteric CH_4 emissions is important to ruminant systems as these emissions are one of the largest sources when considering CO_2e emission prefarm gate or the entire product chain to the consumer. Thoma *et al.* (2013) found that 25% of CO_2e emissions per kilogram of milk were from enteric CH_4 emissions when evaluating the entire 'cradle-to-grave' production chain of US fluid milk production. Beauchemin *et al.* (2010) conducted a whole-farm GHG emissions LCA of western Canadian beef production for an 8-year period using Holos, a whole-farm model developed by Agriculture and Agri-Food Canada. Enteric CH_4 emissions were found to account for 63% of the whole farm emissions of the beef production system that included a cow-calf phase, a feedlot finishing phase, and GHG emissions associated with crop production and emissions from pasture (Beauchemin *et al.*, 2010). The same model was used to simulate whole farm GHG emissions from dairy production in eastern Canada for a 6-year period, and it was found that enteric CH_4 accounted for 48% of total CO_2e emissions (Mc Geough *et al.*, 2012). Consequently, mitigating enteric CH_4 emissions per unit of production for ruminant systems would be one of the most impactful ways to mitigate GHG emissions from ruminant meat and milk production systems.

Dietary manipulation and the use of feed additives are the major ways enteric CH_4 emissions can be directly reduced per animal. Specifically, enteric CH_4 emissions can be impacted by changing the diet's forage-to-concentrate ratio, digestibility, and lipid content. Feed additives that can potentially impact enteric CH_4 emissions include alternative hydrogen sinks (e.g., nitrates and sulfates), ionophores, tannins, saponins, and essential oils. Additionally, attempts have been made to eliminate protozoa from the rumen (known as defaunation) to reduce CH_4 emissions as many ciliate protozoa produce H_2 through their metabolic processes and methanogens are often closely associated with protozoa in the rumen (Finlay *et al.*, 1994). Defaunation has been shown to reduce CH_4 emissions by 20% in sheep (Morgavi *et al.*, 2008); however, the research on defaunation's impacts in live animals is scarce and due to the impractical methods currently available to defaunate a ruminant, commercial adoption of the practice seems unlikely (Hegarty, 1999).

Altering the forage-to-concentrate ratio and the type and digestibility of the carbohydrates of the diet impacts enteric CH_4 emissions by shifting fermentation pathways from acetate production to propionate production. As discussed, higher fiber diets (i.e., high forage-to-concentrate ratio diets) yield

higher proportions of acetate and higher enteric CH_4 emissions. Consequently, ruminants fed diets high in fermentable carbohydrates (e.g., finishing beef cattle in feedlots fed a 75–90% grain diet) produce lower CH_4 emissions per unit of feed intake compared to ruminants fed high forage diets (e.g., grazing cattle and dairy cattle in confinement systems fed 50–60% forage diets). Aguerre *et al.* (2011) demonstrated the impact of the forage-to-concentrate ratio on CH_4 emissions from dairy cattle fed diets from 47% upto 68% forage and found a linear increase in CH_4 emissions per cow per day and per kilogram of dry matter intake with increasing dietary forage percentage.

However, simply decreasing forage consumption of all ruminants worldwide is not a viable, sustainable CO_2e emission mitigation solution for ruminant production systems. Diets very high in fermentable carbohydrates can lead to rumen acidosis resulting in health issues, such as liver abscesses and laminitis (an inflammation of the laminae of the hoof that cause of lameness) (Brent, 1976; Kleen *et al.*, 2003; Owens *et al.*, 1998). However, the efficiency of gain (i.e., amount of feed required for 1 kg of body weight gain) when feeding diets high in fermentable carbohydrates has historically been more economically profitable than high forage diets for ruminant meat animal systems during the finishing phase (the last period of the animal's life before slaughter). Subsequently, most beef cattle in North America are finished in feedlots where they consume high grain diets (e.g., 75–90% corn or barley). However, in recent years due to sustained increases in commodity prices, the profitability of such feeding systems has suffered. Furthermore, ruminants' ability to utilize forages and byproducts (e.g., distiller's grains, cottonseed, citrus pulp, and almond hulls) is a form of valuable nutrient recycling, particularly when considering cellulose (Oltjen and Beckett, 1996). Cellulose is the most abundant organic (carbon-containing) compound on Earth; however, it is indigestible to humans and large-scale, commercial cellulosic ethanol production for use in internal combustion engines is yet to become a reality. Therefore, one of the primary ways humans are able to capture the energy potential of the C fixed via photosynthetic processes of plants is through ruminants and their symbiotic relationship with the microbial populations residing in their digestive tracts. In the context that agriculture at its core is about transforming nutrients and natural resources of low value to humans to higher value food and fiber products, the ability of ruminants to use low protein quality, high fiber feedstuffs and convert them into high quality protein cannot be discounted if we are to meet growing human nutritional needs and should be weighed against the impacts of enteric CH_4 emissions from ruminants.

Lipids included in the diets of cattle has been shown to reduce enteric CH_4 emissions per animal per day (Beauchemin *et al.*, 2009; Odongo *et al.*, 2007), though some of the reduction can be attributed to decreases in intake and digestibility (Beauchemin and McGinn, 2006; Beauchemin *et al.*, 2007). Ruminant diets are typically low in fat ($<5\%$) and increasing dietary fat concentration above 5–6% of the diet can negatively impact rumen fermentation and decrease feed intake (Odongo *et al.*, 2007). Lipids and more specifically, unsaturated fatty acids, can reduce CH_4 emissions via two ways. First, unsaturated fatty acids are saturated by rumen bacteria by a process known as biohydrogenation, which requires H_2 to be used, diverting it from potentially being used for methanogenesis (Ellis *et al.*, 2008). The second, more impactful way unsaturated fatty acids can influence enteric CH_4 emissions is through their toxic impacts directly on methanogens and on H_2 producing bacteria and protozoa (Janssen, 2010).

Alternative hydrogen sinks of nitrate and sulfate reduction can reduce CH_4 emissions because both sulfate and nitrate reducing bacteria compete with methanogens for H_2. In fact, both these processes are more energetically favorable than methanogenesis, but sulfate and nitrate concentrations are often low in ruminant diets (Ellis *et al.*, 2008; van Zijderveld *et al.*, 2010). However, widespread adoption of sulfates and nitrates in ruminant diets currently seems limited in its potential as a enteric CH_4 emissions mitigation technique due to the toxic impacts of some of the intermediates of nitrate and sulfate reduction to the animal (Ellis *et al.*, 2008; van Zijderveld *et al.*, 2010).

Ionophores, such as monensin and lasalocid, can potentially reduce CH_4 emissions by targeting H_2 producing bacteria and protozoa and giving a competitive advantage to propionate producing bacteria, thereby reducing H_2 available for methanogenesis (Russell and Houlihan, 2003). Ionophores are antimicrobials typically fed to cattle to reduce the incidence of rumen acidosis and bloat, and improve feed efficiency (Duffield *et al.*, 2012; Duffield *et al.*, 2008). Past experiments with cattle have shown variable results with ionophores, with some studies demonstrating reductions in CH_4 emissions (Guan *et al.*, 2006; Odongo *et al.*, 2007), while others have not (Grainger *et al.*, 2010; Hamilton *et al.*, 2010). A meta analysis of monensin's impact on CH_4 emissions from beef and dairy cattle found that monensin had a more consistent reduction of CH_4 emissions from beef cattle (−19 g CH_4 per day), which was attributed to the higher concentration of monensin in beef diets (mean dose 32 mg kg^{-1} of dry matter intake) compared to dairy diets (mean dose of 21 mg kg^{-1} of dry matter intake) (Appuhamy *et al.*, 2013). Appuhamy *et al.* (2013) concluded that due to the higher feed intake of dairy cattle, higher doses of monensin may need to be fed to reduce CH_4 emissions, which may be a challenge as the maximum US Food and Drug Administration (FDA) approved daily dose of monensin for dairy cattle is 660 mg day^{-1} or 24 g kg^{-1} of dry matter (FDA, 2006). As some high producing dairy cattle can consume 30 kg or more of dry matter per day, an increase in the FDA maximum dose may be necessary to achieve widespread CH_4 emission reductions from US dairy cattle. Beyond the US, ionophores are restricted in their use or banned in some nations (i.e., the European Union), which limits their global enteric CH_4 emissions mitigation potential.

Tannins, saponins, and essential oils are plant compounds or extracts that have garnered interest as potential enteric CH_4 emission mitigation feed additives that could be considered natural alternatives to antimicrobials. However, with all of these plant extracts little research has been done *in vivo*, with many of the studies that have not showing much promise for mitigation (Beauchemin *et al.*, 2007; Beauchemin and McGinn, 2006; Holtshausen *et al.*, 2009), and few showing a

reduction in enteric CH_4 emissions from ruminants (Mao *et al.*, 2010). A more thorough investigation of these plant compounds' effects in ruminants may be warranted, along with analyses of their cost effectiveness, before they are recommended for feeding as a viable enteric CH_4 emission mitigation strategy.

Attempts to establish acetogens (microbes that use CO_2 and H_2 to create acetate rather than CH_4) in the rumen have been made; however, these organisms cannot outcompete methanogens for H_2, which leaves little potential for their use in mitigating enteric CH_4 emissions from ruminants (Ellis *et al.*, 2008; Lopez *et al.*, 1999). Additionally, attempts have been made to vaccinate ruminants against methanogens with mixed results on enteric CH_4 emissions (Williams *et al.*, 2009; Wright *et al.*, 2004), yet the concept holds promise if further research and development of vaccines is pursued (Krause *et al.*, 2013).

Manure storage

Capturing and reducing GHG emissions through manure storage design and manure treatment offers opportunities to mitigate GHG emissions from animal systems. If manure is stockpiled in solid form (>15% dry matter) with little or no management or treatment, the GHG emission potential from the manure is high (Gilroyed *et al.*, 2011). Manure treatments can reduce GHG emissions, as well as address pathogen load and odors from the manure, which are other areas of concern for animal systems. For anaerobic manure lagoons where manure is stored in a liquid form (<7% dry matter), adding a cover to the lagoon can capture the GHG emitted. By flaring off the accumulated gas containing CH_4, more of the total C emissions are oxidized to CO_2, which reduces the net CO_2e emissions from animal manure. Additionally, covers can allow manure surface crusts to develop (by not being disturbed by precipitation), which some research has suggested allow methanotrophs (organisms that oxidize CH_4 to CO_2) to develop (Clemens *et al.*, 2006; Petersen *et al.*, 2005).

Anaerobic digestion of animal manure has increased in popularity in recent years as a way for farmers to create an on-farm energy source through the production of biogas, which consists of primarily CH_4 (60–70%) and CO_2 (30–40%) (Cantrell *et al.*, 2008). The biogas can then be further refined for use in equipment or combusted to generate electricity that can be used on-farm or put on the grid, which can offset fossil fuel use in the animal system (Asgedom and Kebreab, 2011). However, costs, both for construction and operation, can be a prohibitive factor that can keep animal agricultural operations from adopting anaerobic digestion of manure. For individual operations, the costs can be difficult to overcome, though through public policy efforts it is possible to increase anaerobic digestion capacity of animal manures. The European Union has set a goal of 25% of its energy use to come from renewable sources by 2020, which can encourage further development of anaerobic digestion of animal manure that is already well underway in nations like Germany and Denmark (Holm-Nielsen *et al.*, 2009). In the US, there have been efforts to have utility customers pay a premium for electricity generation, with the premium allowing dairies with anaerobic digesters to cover construction and operation costs (Wang *et al.*, 2011). An evaluation of the program found that grants to offset the initial cost of constructing the digester system were critical for its success, as was sustained cooperation between farmers, the community, utility companies, and government (Wang *et al.*, 2011).

Composting manure is a treatment for solid manures that encourages aerobic decomposition of organic matter, which can reduce odors and pathogen load (Gilroyed *et al.*, 2011). However, composting's potential to reduce CO_2e emissions seems limited or nonexistent (Hao *et al.*, 2004; Hao *et al.*, 2001), which makes it a manure treatment practice that cannot be currently recommended as a way to reduce CO_2e emissions from animal systems (Asgedom and Kebreab, 2011).

Altering the diets of the animals to reduce CO_2e emissions from manure storage systems is a strategy that has tradeoffs and mixed results. In general, the CH_4 emission yield of manure is greatly determined by the manure's volatile solids content, which generally is inversely related with the amount of fermentable carbohydrate in the diet (Hashimoto *et al.*, 1981; Møller *et al.*, 2004). For swine, diets lower in fermentable carbohydrates may result in lower CH_4 emissions from manure; however, the practice can increase the potential of ammonia emissions due to a higher manure pH, which is another undesirable gaseous emission from animal agriculture (Aarnink and Verstegen, 2007).

Production efficiency

After the discussion on ways to reduce GHG emissions via reducing CO_2e emissions per animal per day or from manure per day, other opportunities exist to reduce CO_2e emissions per unit of product through production efficiency. Production efficiency for animal systems can be defined as minimizing the inputs (e.g., feed and fossil fuels) and undesirable outputs (e.g., GHG emissions) required to produce a given quantity of animal product (e.g., pork, beef, and milk) (Place and Mitloehner, 2010). Capper and Bauman, 2013 conducted an excellent review of the role productivity plays on the environmental sustainability that can be referenced for further details. Improved production efficiency can be achieved through increasing productivity (e.g., milk yield and growth), optimizing the productive lifetime of individual animals and populations, and minimizing waste. Production efficiency should not come at the cost of animal health and well-being, as reducing environmental impacts per unit of animal product at the cost of shirking the social responsibility of humans toward animals is not a sustainable solution. However, there is often much overlap between enhancing animal health and well-being and lowering CO_2e emissions per unit of product. Additionally, production efficiency gains can be made within all animal systems by a variety of methods, and therefore, can be seen as a one-size-fits-all solution with a long list of customizable answers depending on the operation, industry, location, etc.

Further explanation of the potential of production efficiency to mitigate CO_2e emissions from animal systems per unit of product can be gained through historical comparisons. Capper *et al.* (2009) compared US dairy production in 1944 with the 2007 system and found a 63% reduction in the CO_2e emissions required to produce 1 billion kilogram of milk for the 2007 system. A similar comparison of the 1977 US beef production system to the 2007 system found a 16.3%

reduction in CO_2e emission per 1 billion kilogram of beef produced for the 2007 beef system (Capper, 2011a). In both industries, reductions in carbon footprint were largely achieved by reducing the number of animals required to produce a given quantity of animal product, which was made possible by advancements in genetics, nutrition, and management. Similarly, when comparing animal systems across nations, differences in those systems production efficiency are translated into different carbon footprints. Gerber *et al.* (2011) demonstrated how carbon footprints can be reduced by diluting out CO_2e emissions across a larger volume of production by conducting a global LCA for dairy production disaggregated by nation. For the 155 countries analyzed, a strong relationship between CO_2e emissions per kilogram of fat- and protein-corrected milk (FPCM) and milk yield per cow was found, with reductions from 10 to 12 kg CO_2e per kilogram FPCM when annual milk yield per cow was 500 kg FPCM to 2 kg CO_2e when milk yield per cow increased to 3000 kg FPCM per year (Gerber *et al.*, 2011).

Continued improvements can be achieved by optimizing an animal's productive life, which impacts the total inputs required to produce a given quantity of animal product. For example, for female animals (e.g., sows and beef cows) that are producing the next generation of food animals, extending the time between parturitions beyond the time necessary (e.g., due to reproductive failure), increases the amount of feed, water, electricity (if housed in confinement), etc. required to maintain those animals. Additionally, extending the time to first parturition for females (e.g., the age at first calving for a dairy heifer) beyond an ideal of what could be achieved with superior genetics, nutrition, and management, increases the animal's lifetime requirements for maintenance inputs. Time-to-slaughter is another example. If meat animals have slow growth rates due to poor genetics, management, environmental conditions, or nutrition, those animals will require a longer life to reach an ideal slaughter weight and composition compared to animals with high growth rates. Consequentially, the slower growing animals will have higher input requirements to create the same amount of product for human use and consumption. The CO_2e emissions associated with those inputs can be viewed as a mitigation opportunity if the productive lifetime and productivity of animals can be optimized. Optimized, rather than maximized, is key. A point of diminishing returns, which would vary by species, management system, and location, will exist both economically and in terms of animal welfare. Health issues associated with productivity (i.e., growth rate) and animal welfare are apparent when examining the broiler industry. Through better nutrition and breeding for faster growth rates and improved feed conversion efficiency (reducing the feed required for 1 kg of growth), a broiler in 2001 took one-third of the time to reach 1.8 kg in weight (32 vs. 101 days) and did so with 3 times less feed (Havenstein *et al.*, 2003). With the gains in efficiency, CO_2e emissions per unit of product (i.e., kg of chicken) have likely declined from the production phase of the entire poultry production chain over time. However, the rapid early growth that these birds achieve has led to an increased incidence of metabolic disorders, including skeletal problems that can lead to deformities and decreased mobility in the later stages of the animals' lives (Angel, 2007). The break point at which a cost to animal welfare overcomes any continued improvements in production efficiency will be influenced by subjectivity of how the welfare of animals is defined and the value animal welfare carries, which will likely change over time and be influence by the society's culture where the animal production system is located.

However, in many cases animal health and well-being are strongly positively related to production efficiency and offer potential opportunities to simultaneously address animal welfare issues and CO_2e emissions of animal systems. The potential for improvement in these issues can be seen in the variability of their prevalence across animal agriculture operations. The dairy industry experiences high rates (30–50%) of clinical lameness in lactating cows, as has been observed on dairy farms in Canada, the UK, and the US (Barker *et al.*, 2010; von Keyserlingk *et al.*, 2012). However, the rates of lameness across farms in these studies ranged widely, which suggests management, facility design, etc. could be altered in those farms with high rates of clinical lameness to achieve the rates seen in the herds of their contemporaries. Lameness can reduce milk yield and productive lifetime of dairy cows (Bicalho *et al.*, 2007; Bicalho *et al.*, 2008), and reduce the productive lifetime of sows (Anil *et al.*, 2009), which represents a potential opportunity to reduce inputs, and their associated CO_2e emissions, from the dairy and swine industries if lameness rates can be improved.

Additionally, heat stress in livestock and poultry is an animal well-being issue that is interrelated with the production efficiency of animal systems. Heat stress occurs when an animal's ability to dissipate heat to its environment is overwhelmed. Heat stress can have far reaching negative impacts on animal growth, lactation, reproduction, and lead to higher rates of mortality (Lin *et al.*, 2006; West, 2003; Wettemann & Bazer, 1985). Often these impacts of heat stress are thought of with regard to their economic impact on animal agriculture industries. St-Pierre *et al.* (2003) modeled the impact of heat stress in the US and found that annual losses to the dairy, beef, swine, and poultry industries cost US$1.7 to US$2.4 billion annually due to decreased productivity and reproduction, and increased mortality. Presumably, the inputs required in all of these industries and the CO_2e emissions associated with those inputs are substantially higher during heat stress to produce a given quantity of animal product. As climate change leads to higher average global temperatures, strategies to mitigate heat stress' impacts on livestock and poultry should be viewed as a way to address both mitigating CO_2e emissions per unit of product and adapting animal systems to climate change.

Indirect Sources Mitigation Opportunities

Opportunities exist both pre- and postfarm gate to mitigate indirect CO_2e emissions from animal systems. Prefarm gate, reducing emissions from feed production represents a major area of opportunity, with soil N_2O emissions from manure and fertilizer application contributing a significant portion of prefarm gate emissions (Ledgard *et al.*, 2011; Rotz *et al.*, 2010; Thoma *et al.*, 2013). Soil N_2O mitigation opportunities revolve around ways to better match, spatially and

temporally, plant N needs with the N supplied. The timing and method of fertilizer and manure applications are important drivers dictating the amount of manure or fertilizer N that plants will uptake versus the N lost to the environment as N_2O emissions. Avoiding fertilizer and manure applications when soils are wet, conducting frequent soil testing to determine agronomic N application rates, and splitting applications to match when plants require N for growth can reduce the potential for N_2O emissions from feed production (Dalal *et al.*, 2003; Millar *et al.*, 2010). Additionally, nitrification inhibitors have been proposed as a way to mitigate N_2O emissions. By inhibiting the conversion of NH_4^+ to NO_3^-, nitrification inhibitors act to limit the amount of NO_3^- available for denitrification and potentially reduce N_2O emissions. Di and Cameron (2003) demonstrated that N_2O emissions from urine patches in grazing systems could be reduced by the application of a nitrification inhibitor; however, the practicality and economics of such a practice likely prevent its widespread adoption (Rotz, 2004). In general, more research on the effectiveness and the causes of variation on N_2O emissions of nitrification inhibitors is needed before they can be recommended as a CO_2e emission mitigation technique (Asgedom and Kebreab, 2011).

Efficiency of fuel use or use of alternative fuels with lower net CO_2e emissions throughout the production chain for transportation and electricity generation (i.e., wind and solar) can lower CO_2e emissions per unit of animal product. Postfarm gate, optimizing transport routes, driver behavior, and transport vehicle design (e.g., low resistance tires and aerodynamic design) can all contribute to decreasing CO_2e emissions from the transportation portion of the animal system product chain (Léonardi and Baumgartner, 2004).

Further reducing refrigerant leakage or switching to refrigerants with lower GWP could help reduce postfarm gate CO_2e emissions from animal systems. Moreover, advancements in packaging that use fewer raw materials in their production and have innovative designs to reduce wasted space during transport and distribution could reduce CO_2e emissions per unit of animal product.

Anaerobic digestion of wastewater at processing plants and abattoirs offers another potential CO_2e emission opportunity, which can both minimize CO_2e emissions from the waste and by reduce fossil fuel-derived electricity use if the biogas is used for electricity generation. Hassan and Nelson (2012) provide an excellent review of the microbiology and biochemistry of anaerobic digestion, as well as the digester designs that can be used for the anaerobic digestion of dairy food wastewater. Similar opportunities exist for livestock and poultry abattoir facilities to adopt anaerobic digestion of their organic wastes (Salminen and Rintala, 2002).

Food waste

Although there has been much discussion and analysis in recent years with regard to the potential climate impacts of changing diets from those higher in animal product content to those lower in animal product content (Garnett, 2011; Jones and Kammen, 2011; Weber and Matthews, 2008), the actual implementation of massive global dietary change seems unlikely, especially in the face of projected increasing worldwide demand for animal products (Garg, 2012). Addressing the issue of wasted edible food would be a more effective approach to reduce CO_2e emissions due to its tangible economic costs to the consumer (Dorward, 2012).

Waste of edible food can be viewed as a total loss. The labor, natural resources, animals, etc., and associated CO_2e emissions, that were required to produce the wasted product have essentially been used and expended for naught as the resulting food has not provided any human nutritional value. Minimizing food waste and waste at all phases of the production chain may be one of the most effective ways to address the paradox of meeting growing global nutritional needs with finite resources. Considering it is estimated that 30% of edible food is wasted worldwide (Gustavsson *et al.*, 2011) whereas there are currently 870 million people (one in eight) in the world who are undernourished (FAO *et al.*, 2012), the reasoning to address food waste goes beyond climate change and becomes a moral issue. Additionally, capturing and converting food waste back into a useful product or energy (i.e., through anaerobic digestion) rather than letting the waste enter a landfill can reduce CO_2e emissions that result from the animal system product chain. In general, reducing food waste and finding ways to convert the waste to into value (i.e., energy) rather than a net source of CO_2e emissions, is not just important sustainability issue for the animal system, but for the entire global food system.

Conclusion

Animal agriculture systems face a challenge in the coming decades to meet growing global demand for animal-derived products with finite resources. Additionally, animal systems must meet growing demand while adapting to climate change and variability, which animal systems contribute to through the emissions of GHG. The sources of GHG emissions from the entire animal production chain (from the farm to the consumer's plate) are varied and derived from microbiological, chemical, and physical processes. Mitigating GHG emissions can come from different strategies of animal feeding, animal management, manure management, and increasing efficiency and reducing waste throughout the animal production chain. Efficiency improvements and reduction of food waste can potentially address the challenges of meeting growing demand and mitigating environmental impacts simultaneously. Ultimately, a concerted, multifaceted global effort that includes farmers, researchers, and policymakers is required to create tangible, positive change surrounding the issues of climate change and animal systems.

Glossary

Carbon dioxide Gas in the atmosphere consumed by plants during photosynthesis.
Chilling hours The duration of temperature below a given threshold required for plants to flower.
Direct effects Effects of climate on plants or animals, for example, direct effect of temperature on plant growth.
Diseases Pathogens in the environment which cause a reduction in growth or reduce the quality of the product.
Indirect effects Effects of climate on an organism which affects the growth or productivity of the economic product, for example, increase in disease pressure induced by climate on a given plant.
Pests A combination of insects, diseases, or weeds which affect either plants or animals.
Plant productivity The rate of generation of biomass used for food, feed, fiber, or fuel consumption.
Precipitation Water which is deposited from the atmosphere onto the earth's surface as either snow or rain.
Soil resources A combination of all the properties of the earth's surface suitable for supporting human activity, for example, agriculture, buildings, and/or roads.
Temperature A numerical measure of heat or cold in an object.

Introduction

In the past 10 years, there has been renewed discussion about the implications of climate change for agriculture. Increasing evidence that our climate is changing and impacting agriculture is leading to understanding of the potential pressures on our ability to ensure an adequate food supply for the increasing human population. Rising carbon dioxide (CO_2), increasing temperatures, and more variable precipitation affect agricultural systems and no region of the world will be exempt from these effects. Understanding these effects on plants will help us develop cropping systems that are resilient to climate stresses and identify adaptation strategies to cope with climate change. Our goal in this article is to provide an understanding of the implications of climate change on cropping systems.

Climate has been changing and during the past 50 years there has been an increase in CO_2 concentration from 325 to 390 ppm with a projection of further increases to nearly 500 ppm by the middle of the twenty-first century (IPCC, 2007a). During the twentieth century, global average air temperatures increased by approximately 0.74 °C (0.56–0.92 °C) (IPCC, 2007a) with projections of further increases in surface air temperatures of between 1.1 and 2.9 °C by 2100 under emission scenarios, which have adopted aggressive methods to reduce CO_2 emissions, and by up to 2.0–5.4 °C under scenarios with higher emission rates. For agricultural cropping systems, trends in average temperature are not as important as the diurnal range, and projections are for increasing minimum temperatures more than maximum temperatures. Winter temperatures have increased more rapidly than summer temperatures, and nighttime minimum temperatures have warmed more than daytime maximums. Across the US (and elsewhere), record high temperatures are three times higher than the number of record cold events (IPCC, 2007a; Meehl *et al.*, 2009). Meehl *et al.* (2007) summarized that on a global basis "it is very likely that heat waves will be more intense, more frequent, and longer lasting in a future warmer climate. Cold episodes are projected to decrease significantly in a future warmer climate. Almost everywhere, daily minimum temperatures are projected to increase faster than daily maximum temperatures, leading to a decrease in diurnal temperature range." Observations of temperature have shown that 10 of the warmest 11 years have occurred since 2001 (Hansen *et al.*, 2012). Coupled with these changes is the decrease in the number of frost days by 10% in the eastern half of the US and an increase in the length of the growing season by over 10 days (Karl *et al.*, 2009). Temperatures are increasing and there are implications for plant growth and also the rate at which plants transpire water because as temperatures increase so does the saturated water vapor in the air creating an atmosphere with an increased rate of water use by crops.

Trends in precipitation are more difficult to assess; however, overall precipitation amounts and heavy precipitation events have increased in most regions of the world; while occurrences of drought has been increasing, particularly since 1970 (IPCC, 2007a; Allison *et al.*, 2009). Karl and Knight (1998) found that more than half of the observed increases in total annual precipitation across the US between 1910 and 1996 were due to increases in frequency of large events (upper 10 percentile of measured daily values). Groisman *et al.* (2005) examined records of measured daily rainfall data across land areas of the world and found trends of increased probability of extreme events for many regions outside of the tropics.

In addition to temperature, precipitation, and CO_2 changing, there is evidence that other components of the atmosphere changing as well. Solar radiation is one of the primary factors affecting plant growth because plants capture sunlight and convert this energy into sugars without which they would not grow. The amount of solar radiation reaching the surface of the earth is affected by cloud cover and the amount of

 doi:10.1016/B978-0-444-52512-3.00003-6

particulates in the atmosphere. Under climate change, there is a projected increase in water vapor (humidity) and more cloud cover, causing a decrease in incoming solar radiation. Observations from around the world have shown that this effect has already begun to occur. Thus, Stanhill and Cohen (2001) found that there was noticeable reduction of nearly 3% per decade over the past 50 years, with current solar radiation totals reduced by approximately 5–7% from the midsummer values in the midlatitude regions. Changes in solar radiation directly affect crop water use and evapotranspiration but have less effect on crop growth because other factors (e.g., water and temperature), often limit productivity (Hatfield *et al.*, 2011). Furthermore, changes in solar radiation are not uniform across any continent and after a thorough evaluation, Stanhill and Cohen (2005) suggested that post-1950 there has been a decrease in solar radiation in the US, with sites in the Northeast, West, and Southwest showing the most significant declines. Solar radiation is more easily estimated by computer simulation models compared with other climate variables, and the use of the models by different researchers has confirmed the observations. A study on solar radiation by Medvigy and Beaulieu (2011) concluded that there was an increase in solar radiation variability around the world related to increases in precipitation variability and convective cloud formation and presence. Any change in solar radiation resources under climate change will affect the agricultural system in different ways and it is important to understand which climate factor is affecting crops.

Changes occurring in the climate are not uniform across any region of the world and it is important to realize that under climate change, variability within and among years, and among locations will likely increase. These changes will create more variation in crop growth and development within individual regions for all of the plant species we depend on for our food, feed, fiber, and fruit supply. Understanding these changes and the implications that flow from them will help us prepare a way to maintain an adequate global food supply. This having been said, agriculture has developed under a changing climate scenario because regional and global patterns of climate have changed and fluctuated since the beginning of cultivated agriculture. The ability of agriculture to adapt to a changing climate is evidenced in the continual increase in crop production throughout the world as exemplified in world maize, rice, and wheat production (**Figure 1**). These increases in production over time also show variation among years caused by the weather. In recent years, notable events including drought and heat waves in Russia in 2010, drought in China in 2012, and droughts in the US in 2011 and 2012, have all had a major impact on agricultural production in these areas.

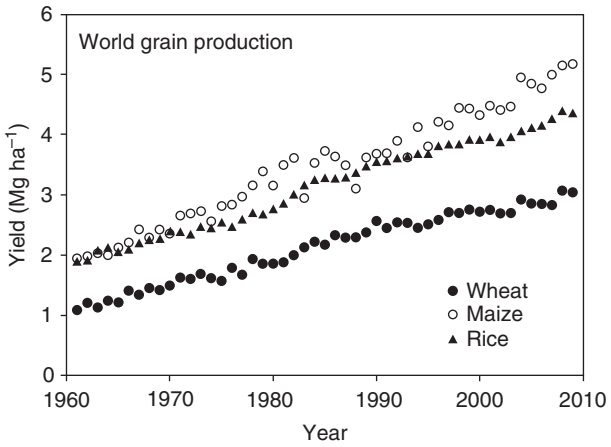

Figure 1 World grain production for wheat, maize, and rice since 1960 (www.fas.usda.gov).

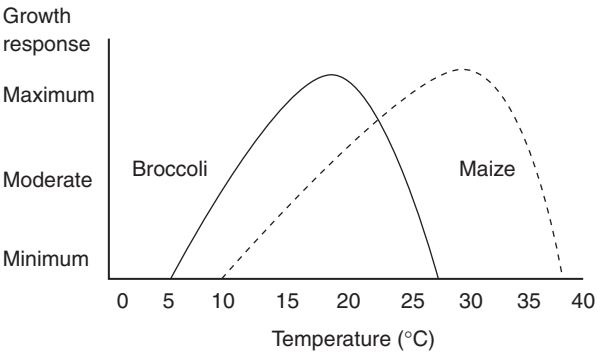

Figure 2 Idealized temperature response for plants showing the maximum, minimum, and optimal temperatures for a warm-season crop (maize) and a cool-season crop (broccoli) (Hatfield *et al.*, 2011).

Climate Parameters: Physiological Effects on Crops

Temperature

Each species responds differently to temperature throughout its life cycle and has a defined range of maximum and minimum temperatures within which growth occurs, and an optimum temperature at which plant growth progresses at its fastest rate. The response of plants to temperature is not symmetrical around the optimal temperature with greater effects of temperatures above the optimum than below (**Figure 2**). Furthermore, there are differences among plants as typified by a cool-season (broccoli) and warm-season (maize) growth response. Growth rates slow as temperature increases above the optimum and cease when plants are exposed to temperatures greater than their maximum. One of the classic methods of describing plant response to temperature has been through the use of a growing-degree-day concept (calculated as growing degree days (GDDs) $= (T_{max} + T_{min})/2 - T_{base}$) where T_{max} and T_{min} are the maximum and minimum air temperatures, respectively, for each day. This approach is commonly used and GDDs calculators are available on the Weather Channel website (www.weather.com) for an individual to evaluate GDDs for their location and compare with average conditions. This approach assumes (1) a base temperature (T_{base}) below which the plant does not grow, (2) the growth rate increases with temperature up to an optimum, and (3) then decreases until the maximum temperature is reached and growth no longer occurs. In most estimations of GDD, temperatures above the maximum are set equal with the maximum and do not detract from growth. Vegetative development usually has a higher optimum temperature than

reproductive development, which means that plants perform best when temperatures are cooler during the development of fruit, grain, or fiber. There are differences among annual (nonperennial) crop species in their cardinal (lower and upper temperature limits) temperature values as detailed in Hatfield *et al.* (2008, 2011).

There are wide ranges in the temperature responses of plants, for example, rice has an optimum temperature of 33 °C for vegetative growth but only 26 °C for reproductive growth; broccoli, a cool-season crop, has range of temperatu res for growth between 5 and 25 °C and 16 and 18 °C for reproductive growth, whereas warm-season tomato has a range for growth between 12 and 30 °C and an optimum for fruit development between 20 and 25 °C. For many plants as air temperatures increase, there is a greater chance that they will be exposed to conditions that exceed their optimum temperature (**Figure 2**).

As temperatures increase, the rate of progression through phenological stages (observable stages of plant development, for example, emergence of the plant seedling from the soil, the first leaf, the first flower, fruit development, and maturity) increases, which typically results in a smaller plant. One critical stage in plant development is pollination during which pollen is shed and flowers fertilized. Pollen is very sensitive to exposure to high temperatures, which renders it infertile and causes a failure in pollination. The predicted increase in more extreme temperature events will cause problems with pollination if they occur during flowering. In rice this means that varieties that flowered early in the morning are better able to tolerate high temperatures than ones that flower in hotter parts of the day (Hatfield *et al.*, 2011).

In other plants particularly many perennials, another effect of temperature is the need for a certain amount of chilling before flowers form. Chilling hours are defined as the hours below a given threshold temperature, usually defined as 7 °C. Chilling hours vary among perennial species, for example, grapes require 400–2000 h, strawberry from 300 to 400 h, and apples between 1000 and 1600 h. As temperatures warm, especially during the winter, the chilling requirements for perennial plants may not be achieved. Luedeling *et al.* (2009) estimated that with the current rate of warming, the chilling hours for the central valley of California would drop from 1000 h to between 500 and 750 h, and that perennial crops requiring more than this amount would not produce fruit. A different response has been predicted in the Northeast US perennial specialty cropping systems. Wolfe *et al.* (2008) analyzed the future chill requirements of the Northeast and found that a 400-h chilling requirement will continue to be met for most of the Northeast during this century regardless of emissions scenario. However, crops with larger chilling hour requirements (>1000 h) could be negatively affected, particularly in southern sections of the Northeast. Yields will be negatively affected if the chilling requirement is not completely satisfied because flower emergence and viability will be low.

According to Wolfe *et al.* (2008), an extended frost-free period projected for the Northeast will benefit perennial specialty cropping systems requiring a relatively long growing season, such as apples, peaches, and grapes. The warmer winter temperatures produced a longer frost-free period allowing for earlier growth in the spring; however, these warmer temperatures caused a more variable fruit set in the spring. Increased summer heat stress and drought could reduce yield and crop quality in fruit crops. Wolfe *et al.* (2008) found that apple yields for western New York (1971–82) were lower in the years when winters were warmer than average (based on accumulated degree days >5 °C from January 1 to budbreak). Midwinter warming can lead to early bud burst or bloom of some perennial plants, resulting in frost damage when cold winter temperatures return. Warm temperatures also affect fruit quality, and perennial crops exposed to high temperatures during fruit development produce smaller fruit and poorer quality.

One effect of increasing temperatures is to increase the transpiration rate of the plant. Water use or transpiration is affected by the amount of solar radiation intercepted by the plant canopy, windspeed, vapor pressure gradient between the plant and the atmosphere, and the amount of water available to the plant. The vapor pressure gradient is affected by air temperature because the maximum amount of water the air can hold is a positive exponential function of air temperature. This effect causes plants to use water more rapidly and without an adequate supply plants rapidly show signs of water stress, such as wilting, rolling of the leaves, or in severe cases of water shortage, death.

Precipitation

Precipitation supplies water to the soil from which plants extract water. Precipitation is one of the most difficult climate parameters to predict into the future; however, there is evidence that precipitation events will be more intense and there may be shifts in its seasonality. Across the Midwest US, the projection is for more precipitation to occur in the spring and for a reduction in summer. These shifts have significant implications because Midwestern cropping patterns have developed to utilize the precipitation occurring during the summer and any decline during that period reduces the available soil water leading to a reduction in plant growth. As the water supply in the soil is reduced, the plant is no longer able to extract sufficient amounts of water and stomates begin to close. As they close they no longer allow water to exit (thereby reducing cooling benefits), while also limiting the amount of CO_2 that enters from the atmosphere into the leaf. Without CO_2 being converted into sugars in the leaf, the plant is no longer growing and productivity suffers.

Because the plant is dependent on the soil to supply the water needed for plant growth, there is an important role for soil in response to climate change. Soils absorb and hold water because of their organic matter content and high-quality soils with large amounts of organic matter store more water. Organic matter content in soils is replenished by adding organic material and avoiding excessive tillage. These processes have been recently reviewed by Hatfield and Wright-Morton (2013) in which they discussed how soils become marginal in their functionality because of the loss of organic matter content and erosion. Maintenance of the soil to increase water availability can help reduce the impact of the increasing uncertainty in precipitation. Soil management to decrease the potential for erosion from the increased intensity of precipitation events will be necessary to maintain crop cover either as growing

plants or as crop residue on the surface to protect the soil surface from the impact of rain during these intense storms.

Changing precipitation patterns and intensity will affect soil erosion. Precipitation causes erosion through the interacting effects of storm energy and maximum prolonged precipitation intensity (Nearing *et al.*, 2005). The dominant variable causing erosion is rainfall intensity, the amount of rainfall reaching the soil surface per unit time, rather than total rainfall amount (Nearing *et al.*, 2005). Soil erosion processes are affected by (1) erosive effects of rainfall, irrigation, snowmelt, and wind; (2) plants, cropping, and management; (3) soil erodibility; (4) conservation practices; and (5) topography. Climate change and the impact on precipitation frequency, intensity, and seasonality will most likely have the greatest effects on the first three of these factors. O'Neal *et al.* (2005) showed there was a relationship between expected patterns of precipitation under climate change and crop management practices. Agricultural production depends on a high-quality soil resource and degradation of the soil via erosion will limit the ability to continue to efficiently produce crops. To offset these potential impacts in the future, agriculture will have to aggressively utilize conservation practices to provide protection to the soil (Delgado *et al.*, 2011).

Supplying water to the soil via irrigation can offset the effects of inadequate precipitation or timing of precipitation with crop water demand. An example of the timing issue occurs in the Central Valley of California, which has a Mediterranean climate in which virtually all precipitation occurs during the winter. To produce a crop, water must be stored from the winter period and then supplied to the soil during the summer. In many areas of the world, irrigation from ground water or surface water storage is used to supplement precipitation during the growing season. However, given the requirement for increasing amounts of fresh water to support human activities, agriculture will have to become more efficient in its use of water for production.

Carbon Dioxide

Carbon is one of the fundamental building blocks for all plant compounds. Through the process of photosynthesis, CO_2 is converted into sugars which are ultimately converted into proteins, starches, amino acids, etc. through a variety of metabolic processes. Rising levels of CO_2 in the atmosphere has a positive effect on plant growth and development. Even using conservative estimates, the current levels of approximately 390 ppm will increase at a faster rate than originally expected to nearly 450–500 ppm by 2050 (Karl *et al.*, 2009). To assess the effect of increasing CO_2 on plant growth, enclosed chambers and free-air CO_2 enrichment (FACE) studies have been conducted in which plants have been exposed to higher levels of CO_2 typical of what may be expected in future climates. These studies have shown a positive effect on plant growth (Kimball, 1983, 2011) with increasing CO_2 concentrations increasing growth by ~10% in plants such as maize and sorghum, which already have the highly efficient C_4 photosynthetic pathway, to increases in growth of greater than 30% in C_3 plants, such as beans, peanut, rice, wheat, soybean, and others. In general, doubling CO_2 caused an approximate 30% increase in reproductive yield of C_3 species and a less than 10% increase for C_4 species. Differences among the species are due to differences in internal metabolic pathways that determine how the plant incorporates CO_2 into sugars and how respiration processes (release of CO_2 from metabolic processes) release CO_2 into the cells.

Respiration is the process of converting C-based compounds back into CO_2 – a process that occurs in all living organisms. Although the process of photosynthesis is controlled by the amount of solar radiation, respiration is controlled by temperature. In biological studies, the Q_{10} temperature coefficient measures the rate of change in biological activity, for example, respiration, for every 10 °C change in temperature. For most biological systems this coefficient ranges between 2 and 3. Thus there is a doubling of respiration rate for every 10 °C rise in temperature, so that as the air temperature increases there is a concomitant increase in the respiration rate. The importance of this response is because nighttime temperatures are increasing more rapidly than daytime temperatures, which are likely to lead to higher respiration rates in plants. Higher respiration rates will result in lower plant growth because CO_2 that is captured during the day will be released back into the atmosphere at night rather than being utilized for growth. Plant temperatures at night tend to equal air temperatures so that any increase in air temperature directly affects respiration rate. The implication of the effect of climate change on respiration is a significant challenge to increasing plant productivity.

One of the interesting aspects of the plant's response to increased CO_2 links photosynthesis with transpiration. Increasing CO_2 decreases the transpiration rate of the plant while increasing the photosynthetic rate. This effect occurs because the CO_2 concentration gradient is larger than that for water vapor between the leaf and the atmosphere, and there is actually a decrease in the stomatal opening causing a reduction in the rate of movement of both gases. The net effect of this change is to increase water use efficiency, meaning that plants grown under high CO_2 concentrations have higher photosynthetic rate than transpiration rate. Observations from scientific studies around the world have shown that a doubling of CO_2 reduced stomatal conductance by nearly 34–40% (e.g., Kimball and Idso, 1983; Morison, 1987; Ainsworth *et al.*, 2002) so that an atmospheric CO_2 concentration of approximately 450 ppm, as estimated to occur between 2040 and 2050, will likely cause 10% reductions in stomatal conductance. The magnitude of these reductions in stomatal conductance will lead to decreases in transpiration and have potential positive impacts on crop water use efficiency, that is, they will be more water use efficient in the amount of growth they make relative to their rate of water use.

The effect of reduced water use by plants will be especially important in rainfed environments where plant growth is dependent on rainfall during the growing season. This effect has been observed in field conditions by Bernacchi *et al.* (2007) where they found soybean plants grown under ambient CO_2 (control plants) showed a large reduction in water use when their water supply decreased. In contrast, plants grown under increased CO_2 (FACE plots) continued to transpire because of the water conservation compared with control plots. This allowed plants in the FACE plots to continue to photosynthesize and grow for a few days longer, whereas the control plants ceased growth. Under rainfed agriculture, which often

experiences periods of drought, the net impact of elevated concentrations of CO_2 would be to enable conservation of soil water, thus sustaining crop productivity for longer than at today's CO_2 levels. Understanding these relationships between ambient environmental conditions and plant physiology helps to develop production systems, which can cope with the increasing stress levels likely to occur under climate change.

Ozone

Although attention has been directed toward CO_2 increases as part of climate change, less attention has been given to ozone (O_3), although concentrations of this gas have increased in rural areas of the US over the past 50 years, and are expected to increase further over the next 50 years. Currently, Midwest and Eastern US have some of the highest rural O_3 levels on the globe. Ozone concentrations increase toward the east and south, showing levels in Illinois exceed those in Nebraska, Minnesota, and Iowa. Only Western Europe and Eastern China have similar (high) levels. Argentina and Brazil and most of the Southern Hemisphere have much lower levels of O_3, and expect to see little increase in O_3 over the next 50 years. Increasing O_3 levels will impact crop production, and efforts to increase O_3 tolerance will be important to maintain agricultural productivity. Future trends in global O_3 concentrations are linked to Intergovernmental Panel on Climate Change scenarios, so that agricultural impacts from O_3 can be considered along with the other components in climate change. Modeled predictions for O_3 based on expected economic development and planned emission controls in individual countries estimate significant increases in the annual mean surface O_3 concentrations in major agricultural areas of the northern hemisphere (Dentener *et al.*, 2006).

Physiological responses to increased O_3 concentrations have been studied using similar approaches to assessing the effects of increased CO_2. After uptake through the leaf's stomata, ozone interacts with plants' cellular processes, inhibiting photosynthesis, growth, and yield. Detrimental effects result from a combination of chemical toxicity and physiological responses that either amplify or inhibit injury and in many regions of the US and worldwide (Booker *et al.*, 2009; Morgan *et al.*, 2006) current ambient O_3 levels are already impacting yields of crops such as alfalfa, bean, clover, cotton, peanut, potato, rice, soybean, sugar cane, and wheat. In some grass species, changes in leaf chemistry from elevated O_3 exposure have caused reduced nutritional quality of the grass used to support grazing animals. This loss of nutritional quality in these grasslands may be more significant than biomass losses (Muntifering *et al.*, 2006). Ozone changes are often not considered part of the climate change puzzle; however, the changing temperature and humidity of the atmosphere combined with continued fossil fuel combustion will create conditions favorable for O_3 formation and higher atmospheric concentrations.

Crop Growth and Yield Response to Climate Change

Grain crops

Grain crops, for example, wheat, oats, rice, corn, soybean, and beans, all have different responses to a changing climate

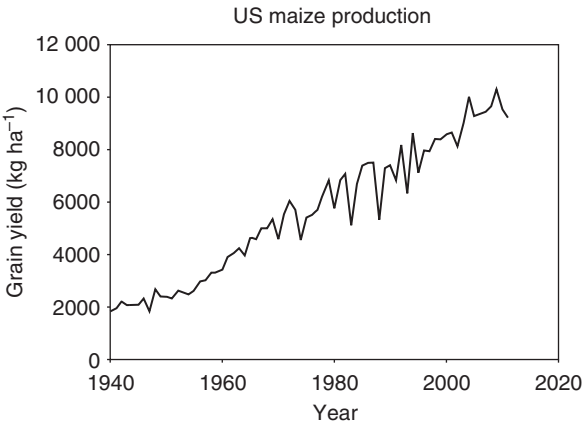

Figure 3 Variation in annual corn (maize) yields for the United States to demonstrate the effect of weather variability among years (USDA-NASS, 2013, www.nass.usda.gov).

(Walthall *et al.*, 2012). Examination of among-year yield variation shows that within-year weather conditions have an impact on production. Most of this reduction in grain yield is associated with the lack of sufficient water to maximize grain production and exposure to the short-term water deficits may reduce yields from their potential by 5–20% (Hatfield, 2010). Increasing variation in rainfall across many areas of the world may exaggerate the effect of climate change on grain production because of the increased frequency of water stress during the growing season. This effect will be increased in soils with lower water-holding capacity or eroded topsoil because the limited amount of soil water available to the plant during the growing season (Hatfield, 2012; **Figure 3**).

There is evidence that the increasing temperatures over the past 20 years have already begun to impact growth and Lobell *et al.* (2011) suggested that yield declines from 4 to 5% have occurred in many growing areas of the world. Other studies have suggested that maize yields in the Midwest US would decrease 2 to 3% with a temperature increase of less than 1 °C (Hatfield *et al.*, 2011). Grain yield of soybean demonstrate a differential response to changing temperatures by region depending on where the projected temperatures fall on the growth response to temperature relationship (**Figure 2**). In the southern US, soybean yields are projected to decline because temperatures will begin to exceed maximum temperatures for optimal growth, whereas in the Midwest, soybean yields will increase because rising temperatures will actually benefit the plant (Hatfield *et al.*, 2011). In an evaluation of the likely impacts of temperature change in the Central Valley of California, Lee *et al.* (2011) found that all crops except alfalfa showed a decline in production as temperatures increased. Decreases in production were as large as 30% by 2100 because of increased temperature stress on the plant and disruption of optimum physiological function.

Winter wheat and other small grain crops exhibit a large sensitivity to increasing temperatures. The warmer the temperatures, the faster the rate of development leading to reduction in grain yield. An interesting observation in wheat is the decline in grain quality with the changing climate and an associated emerging challenge will be to understand and

quantify these impacts. It has been observed that growing wheat under low nitrogen (N) conditions coupled with high CO_2 reduced grain quality, and a steady decline in grain protein in Australia from the late 1960–2000 was related to increasing CO_2 concentrations (Conroy and Hocking, 1993). Other research results on barley have concluded that nutritional and processing quality of flour will diminish for cereal grown under elevated CO_2 and low N fertilization. These observations point out the need to increase our understanding of these interactions because they will provide insights into crop response to climate change and how we can ensure nutritional quality of grain production under climate change. The quality of grain is not the only product affected by climate change, in cotton, there is a decrease in fiber quality when plants are exposed to high temperatures during boll development when lint fibers are being formed (Pettigrew, 2008).

Forage crops

Forage grasses exhibit the same responses to temperature as other plant species; however, grasslands are made up of mixtures of plants and rising temperatures may cause a change in the relative dominance of different species in the community. These changes in community structure have been discussed and evaluated relative to climate change by Izaurralde *et al.* (2011). The quality aspect of forages is even more critical than in grains because of the direct consumption of the forage as the primary source of nutrition for the animal. Efficient animal production from pastureland and rangeland systems depends on both forage quality and quantity. Positive and negative changes in forage quality are possible as a result of atmospheric and climatic change when we examine the potential vegetation changes and environmental effects on forage protein, carbohydrate, and fiber content. Studies on forage quality have helped to reveal the linkage between changing CO_2 concentrations and a plant's ability to extract N from the soil. Warming temperatures cause N concentrations in the forage to decrease partially because of the positive effect of increasing CO_2 on enhancing vegetative growth (Morgan *et al.*, 2004). The fact that these effects will vary among species highlights the need to understand interactions among all the plant species in a community and how they respond to climate change.

Forage growth is directly linked to precipitation because many of the production areas are in regions with limited precipitation during the growing season. Increasing variation in precipitation will lead to increased variation in forage production which, in turn, will affect livestock production. These variations in forage production will have worldwide impacts on animal production.

Specialty crops

Annual specialty crops include many vegetable and fruit plants, each with their own environmental ranges. Climate change will have an impact on them in a similar way as grain crops; however, because these crops are often directly consumed, the effects of temperature or water stress are more noticeable.

Temperature is a major environmental change expected to affect production of annual specialty crops as temperature responses vary more widely among specialty than other crops, for example, tomatoes have a warmer temperature response than cool-weather crops, such as broccoli, potato, lettuce, and onion (Hatfield *et al.*, 2008). The sensitivity of these different species to stress depends on when during the life cycle the stress is imposed and the nature of the stress itself for example, periods of hot days, overall growing season climate, minimum and maximum daily temperatures, and timing of stress in relationship to developmental stages. In specialty crops, mild heat stress (a 1–4 °C above optimal growth temperature) often results in moderate reductions in yield (Timlin *et al.*, 2006; Tesfaendrias *et al.*, 2010; Walthall *et al.*, 2012). Specialty crops are vulnerable to exposure to high-temperature stresses during pollen development, which typically occurs 7–15 days before pollination. The pollination period is critical to the development of fruit and exposure to temperature extremes and intense heat stress (>4 °C over the optimum temperature) during this period may cause a failure in fruit set and consequent yield loss (Tesfaendrias *et al.*, 2010; Walthall *et al.*, 2012). Protection of the plants against exposure to high temperatures during this phenological stage may be a critical step in ensuring fruit or vegetable production.

Water is a critical component in specialty crop production and maintaining an adequate water supply is necessary to achieve high yields and product quality acceptable for consumers. Observations in strawberry have shown that inadequate water results in reduced leaf area, root development, and smaller berries causing less harvestable yield (Bordonaba and Terry, 2010). Potato production is reduced when plants are grown under water stress coupled with high temperatures because the plant is unable to maintain the optimal level of starch production needed for tuber development. Each crop species has a different amount of water required to produce fruit, for example, tomato, 2.58–11.88 kg m^{-3}; potato, 1.92–5.25 kg m^{-3}; melon, 2.46–8.49 kg m^{-3}; watermelon, 2.70–14.33 kg m^{-3}; and cantaloupe, 4.18–8.65 kg m^{-3}. This suggests that future efforts will have to be directed toward management practices that can maintain water supplies to these crops. In many specialty crop production regions, there is extensive use of irrigation to avoid water stress.

Perennial crops

Perennial crops are typically considered as those that are more permanent, requiring a number of growth cycles before fruit is produced. One of the characteristics of these plants is their requirement for winter chilling before flowering the next spring. As discussed earlier in the Section Temperature, there is evidence that with warming winter temperatures some perennial crops may not have their chilling hour requirement satisfied, which will limit flowering and ultimately fruit set. An additional concern is that warm winters may promote early bud and flower development and late season frost events will damage these flowers and fruit or nut formation. Perennial crops are valued for a combination of their total production and the quality of the harvested product, for example, size of a peach or apricot, the red blush on an apple, oil content of olives, or the quality of wine produced from a particular vineyard. By nature, perennial crop production is long-term and climate change will create interesting problems for production because production areas have less flexibility in their location after establishment and because the production

cycle is often measured in decades rather than single growing seasons.

Apples provide an excellent example to show how climate stress will impact growth throughout the year and across years. High temperatures occurring during the year before harvest affect floral initiation (occurs in June–July) and can reduce the number and vigor of potential floral buds. When the tree is dormant, exposure to extreme cold can kill buds and intermittent warming periods can cause flower buds to be more susceptible to winter damage before growth resumes in spring. Flowers can emerge too early in the spring and if frost occurs, will be killed. During the development of fruit in the spring, exposure to high temperature reduces cell division causing smaller fruit size. During the summer months, high temperature may cause sunburn damage reducing harvest quality, accelerating maturity, reducing fruit firmness and color development, and/or decreasing the suitability of fruit for short- or long-term storage. These effects will be exaggerated if there is an occurrence of water deficit during the same period. It is often not recognized that climate stress may occur at multiple times during the growing season; however, in perennial crops this is a common phenomenon.

Indirect Effects of Climate Change on Crops

Plant production is affected by a combination of direct impacts from different climate variables and indirectly for example, insects, diseases, and weeds, which are themselves directly impacted by these same climate variables. The indirect effects may have as large an impact on productivity as the direct impacts and also affect the quality of the fruit, grain, or feed from these plants. To fully appreciate the impacts of climate change on plants it is important to understand the indirect impacts on plants.

Insects

Increasing air temperatures are beneficial to insect pests and like plants, rising temperatures accelerate every aspect of an insect's life cycle, and warmer winters reduce winter mortality. Insects, like plants, have an upper threshold of temperatures above which there is mortality. Similar to plant response, warming temperatures will cause some insects to thrive and expand their range, whereas others will have a reduced viability. Warmer temperatures during the summer increases the growth of insect populations; however, a more positive benefit on insect populations is caused by lengthening of the growing season, which results in more damage to plants (Bradshaw and Holzapfel, 2010). Increasing air temperatures also affect the range of insects because they encounter a wider range of environments in which they can survive; however, each insect species has a specific range of temperatures in which it develops, so not all insect populations will automatically expand with warmer temperatures. Insects also require water for survival and limited water supplies will affect populations.

Temperature plays a large role in the geographic ranges of insect pests because of the impact it has on the ability of insects to survive winter conditions and the presence, and nutritional quality of the plants upon which they feed. Insects are mobile and both local dispersal and long-distance migration allow some to invade colder regions. Spring emergence is generally defined by temperature, whereas winter dormancy is cued by photoperiod or a combination of photoperiod and temperature. Insects are capable of withstanding all but the most extreme precipitation events, thus rainfall affects growth and survival principally through increased cloud cover, which can reduce activity, and changes in the nutritional quality of plants. Insects, especially small ones and those with aquatic life stages, will desiccate and die without ready access to water. Humidity influences the prevalence of insect diseases, as well as plant diseases that insects carry.

Increasing air temperature results in reduced cold stress over the winter and when there is no substantial increase in heat stress during the summer, which will affect insect life cycles and survival by removing temperature stress during the winter period allowing greater insect populations to be maintained (Bradshaw and Holzapfel, 2006). Decreased soil temperatures can occur in areas with reduced frequency of snow cover leading to greater winter insect mortality (Bale and Hayward, 2010) because arousal from winter dormancy is generally dependent on accumulated temperature (growing-degree days). Increasing air temperatures are causing phenology to advance faster than previously observed within a growing season (Gordo and Sanz, 2006; Harrington *et al.*, 2007; Gregory *et al.*, 2009; Bale and Hayward, 2010). This is a similar response to that observed for plants with warmer temperatures causing faster rates of development. The effect of the longer growing season has caused some insects with multiple generations per season to produce more generations per year (Tobin *et al.*, 2008; Altermatt, 2010). However, as for crops, insects have optimal temperatures under which they thrive, so not all insect populations will increase with increasing temperature.

Diseases

Leaf and root pathogens will be favored by increases in humidity and the frequency of heavy rainfall events projected for many parts of the world will create a more conducive environment for many different pathogens (Garrett *et al.*, 2006, 2011). Increases in temperature also favor populations of pathogens because the growth rate of these organisms is temperature dependent. Incidences of warm, moist environments will increase the potential for disease to occur on plant leaves and fruit (Wu *et al.*, 2011). However, it is difficult to develop general statements that the incidence of pathogens will increase because even, short- to medium-term droughts reduce the duration of leaf wetness causing a reduction in pathogen attack on leaves. The development of a better understanding of the effect of climate change on pathogens remains a challenge for agriculture and a major topic for future investigation. Protection of the growing plant, and the harvested product placed into storage, from pathogens remains a challenge. Improving our understanding of the role climate has on these organisms will increase our ability to ensure a secure food supply for the future.

Weeds

Weed species are a range of plants which exist within plant production systems that compete with crops for water, light,

and nutrients while often also serving as hosts for some pathogens or insects. Weeds have a much greater response to increasing CO_2 concentrations than has been observed in cultivated plants (Ziska, 2004). This implies that weed management may become more difficult because weeds will become more vigorous and invasive under climate change and thus lead to greater impacts on plant productivity (Ziska, 2010). Temperature controls weed species success with the same effects on weeds as on cultivated plants (Woodward and Williams, 1987). A warming climate will affect the dissemination of weeds with subsequent effects on their growth, reproduction, and distribution. Indeed, warmer temperatures, in particular an increase in the number of frost-free days, may allow a northward expansion of aggressive weeds into areas where weed populations have been less of a problem in the past. Weed management under climate change will become more of a challenge because of the nature of these plant species and their positive response to warming temperatures, more variable precipitation, and increasing CO_2 concentrations.

Adaptation in Cropping Systems

Ensuring future supplies of food, feed, fiber, and fruit depends on our ability to develop adaptation strategies to allow plants to cope with climate change. In this quest it is important to remember that we are dealing with complex biological systems, which respond to a range of different factors and that within each species there is a wide range of response. Adaptation science is just beginning to emerge and climate change will present a challenge to our ability to not only quantify the responses of different species to climate variables, but also develop and evaluate methods that can be employed to reduce the negative effects of climate stress on plant growth and yield. There are two avenues whereby we can address this problem, we can evaluate differences in genetic responses to different climate variables or determine the role of management practices to alleviate or avoid the effect of climate on plants.

Genetics

All species show a range of genetic responses to selection pressures. Tolerance of plants to high temperatures can be assessed by evaluating phenotypic traits that promote heat tolerance during flowering, increased harvest index (ratio of reproductive production to total biomass production), smaller leaves, or diverting more growth into root systems to increase water uptake. One adaptation strategy would be to select plants for peak flowering times in cooler periods of the day to assist pollen survival and increase grain set (Prasad *et al.*, 2006). Another selection target would be to identify plants that demonstrate different recovery responses to high temperature or water stress. Observations that plants show increased transpiration efficiency with increasing CO_2 suggest that there may be genetic differences in these responses; however, these relationships have not been fully evaluated to determine if there is potential in genetic variation to achieve enhanced transpiration efficiency through genetic manipulation.

Assessing the genetic response of plants to climate variables has not been the focus of many studies partly because they require specialized facilities capable of inducing temperature and water stresses typical of future climate scenarios on a range of genetic stock within a species. As we continue to develop more detailed gene maps of different species, there is optimism that these tools will help identify genes or gene sequences associated with responses to climate stress.

Management

Management as an adaptation strategy offers the most immediate promise to alleviate the effects of climate change. One obvious management strategy is to provide water by irrigation to supplement inadequate precipitation. Irrigation has proven very effective in many parts of the world and efforts to increase irrigation use efficiency and reduce waste have proven beneficial to enhancing production under limited water supplies. Use of drip or trickle irrigation to supply water only to the plant has shown promise in many parts of the world. However, for irrigation to be effective there has to be an adequate supply of surface or ground water to meet crop demands.

Other management practices involve changes in planting dates so that plants grow and mature during times of the year with reduced probability of high temperature or water stress. There are limits to the range of potential planting dates in many environments because plant growth may be limited by cold in the early spring if the temperatures are below the lower threshold for development (**Figure 2**). A more simple management approach may be to alter plant selection and grow plants which have a different temperature response curve. An example of this would be to produce wheat or other small grain, which can be planted in the fall and matures in the early summer before the primary occurrence of high temperatures or increased water demand, in place of corn, which is planted in the spring and is producing grain during the warmest and least rainy period of the year in a number of environments. Another alternative would be to replace corn with sorghum or millet, which is much more tolerant of water stress conditions than corn, and under water limited environments performs better in producing a grain. In many arid environments these types of management decisions offer the potential for ensuring a grain supply.

There are observations collected from ongoing research on grain quality, which suggests that management of nutrient supply for plants should be considered in adaptation strategies to cope with climate stress. Nutrient management is a portion of the soil management complex, which may hold some keys to helping build more resilient crop production systems to the changing climate. As part of the soil management complex, we need to ensure that soils have maximum water-holding capacity and nutrient cycling capabilities because these are related to negating the negative effects of climate stress on plant growth and development. Strategies to achieve these goals were recently reviewed by Hatfield *et al.* (2011). There is no single solution to this problem and development of effective adaptation strategies will require efforts which integrate across a number of approaches.

Conclusion

Climate change is occurring with the expectation for increased temperatures, more variable precipitation, increasing CO_2,

increasing O_3, and higher humidity over the next few decades. Agriculture has been subjected to climate change in the past and we have evolved our production systems to cope with interannual and annual variations in weather. The concern is that the rate of climate change and the magnitude of the change may begin to exceed the capacity of some plant species to adapt resulting in a decline in production. To place this in perspective, recent analysis for the impacts of increased temperature on wheat production in India by Ortiz *et al.* (2008) shows the fragile nature of our production systems. The consequences of increasing temperatures, which are in the moderate range of those suggested by climate scientists, would create a shortage of wheat production in India and cause the transition from a self-sufficient country to an importer of wheat to meet population demands.

Climate change impacts all plant growth and productivity and understanding how to develop production systems, which can cope with the increasing temperature and water stress offers a challenge to be able to maintain adequate food supplies for the increasing population. The effects of different climate variables on plant growth, development, and yield demonstrated shows where we need to begin to focus our efforts to meet this challenge.

Glossary

Chilling requirement Minimum quantity of exposure to cold temperatures required to break dormancy allowing the tree to flower normally.
Evapotranspiration The sum of evaporation and plant transpiration from the Earth's land surface to atmosphere.
Phenology The study of periodic plant and animal life cycle events and how these are influenced by seasonal and interannual variations in climate.
Photoinhibition Description of reactions that decrease the efficiency of photosynthesis.
Transpiration The loss of water vapor from parts of plants, especially from leaves but also from stems, flowers, and roots.

Introduction

Horticulture Species Range

The horticulture industry is represented by a diversity of perennial and annual crops, ranging through fruits, nuts, vegetables, edible fungi, and extractive crops (essential oils), with amenity horticulture, cut flowers and turf also categorized as horticultural crops. Globally, in 2010 approximately 600 million tons of fruit, 9 million tons of tree nuts, and more than 1.7 billion tons of vegetables were produced (FAOSTAT, 2012). In contrast to many other agricultural industries, horticultural products are of high value and are often grown on relatively small areas of land and under dry-land, irrigated, or covered conditions. There often exists a high level of management input aimed at ameliorating climate risks (e.g., via irrigation) despite this, many activities retain considerable exposure.

Horticulture Geographical Range

Horticultural crops are grown across most latitudes in the world with representations from temperate and Mediterranean (30–40°), subtropical (20–30°), and tropical (0–20°) regions. Because of the nature of horticultural products, transport over long distances can require refrigeration and become expensive. So, where possible, much horticultural production is undertaken in proximity of population centers, and are therefore also at risk from urban expansion. Horticultural production can range from vast enterprises, family owned farms, to plantings by individuals in their own gardens.

An overall increase in horticultural production has been observed over the recent past, driven by demand from rapid population increase and facilitated by the introduction of trade agreements and the emergence of an international horticultural market (Dehnen-Schmutz *et al.*, 2010). A marked increase in production from the Asian region for fruits, tubers, and vegetables has been contrasted by a decline in European production (**Figure 1**). Over recent decades since 1980, there has been an increase in exports from developing countries like Africa (Mathooko and Mutui, 2011) and Asia (Xue and Revell, 2009). China, for example, ranked second in the world as an exporter of processed vegetables and fourth for unprocessed vegetables in 2005 (Xue and Revell, 2009). Some production declines in cooler growing regions of Europe have been related to increasing oil prices affecting costs of greenhouse heating. Increasing labor costs, and in some countries a shortage of seasonal workers, has also been a factor in productivity decline in Europe (Dehnen-Schmutz *et al.*, 2010).

Horticulture Economic Importance

In 2010, global horticulture produce made up approximately 43% of gross production value of crops (approximately US $600 billion), with US$255 billion for fruits and nuts, and US $370 billion for vegetables (FAOSTAT, 2012). Key fresh fruit species (in order of production tonnage in 2010 and representing all fruits above 1% of world production) include bananas, watermelons, apples, oranges, grapes, mangoes/mangosteens/guavas, plantains, other melons (including cantaloupes), pears, tangerines/mandarins/clementines, peaches and nectarines, pineapples, lemons and limes, papayas, and plums and sloes. The production rankings of these vary by region. Key vegetables (in order of production tonnage in 2010 and representing all vegetables above 1% of world production) include potatoes, cassava, tomatoes, sweet potatoes, onions (dry), cabbages and other brassicas, cucumbers and gherkins, yams, eggplants (aubergines), carrots and turnips, chilies and peppers (green), lettuce and chicory, pumpkins, squash and gourds, garlic, spinach, green beans, cauliflowers and broccoli, and green peas (FAOSTAT, 2012; **Table 1**).

Flowers, turf, and amenity horticulture are also important horticultural production entities. In Australia, turf production (sod) in the 2005–06 growing season has been estimated to have been worth AUS$213.8 million and future growth in this industry is expected (Aldous and Holborn, 2012). The United States is the third-largest producer of cut flowers in the world and production was valued at US$424 million in 2001 (Bonarriva, 2003).

 doi:10.1016/B978-0-444-52512-3.00240-0

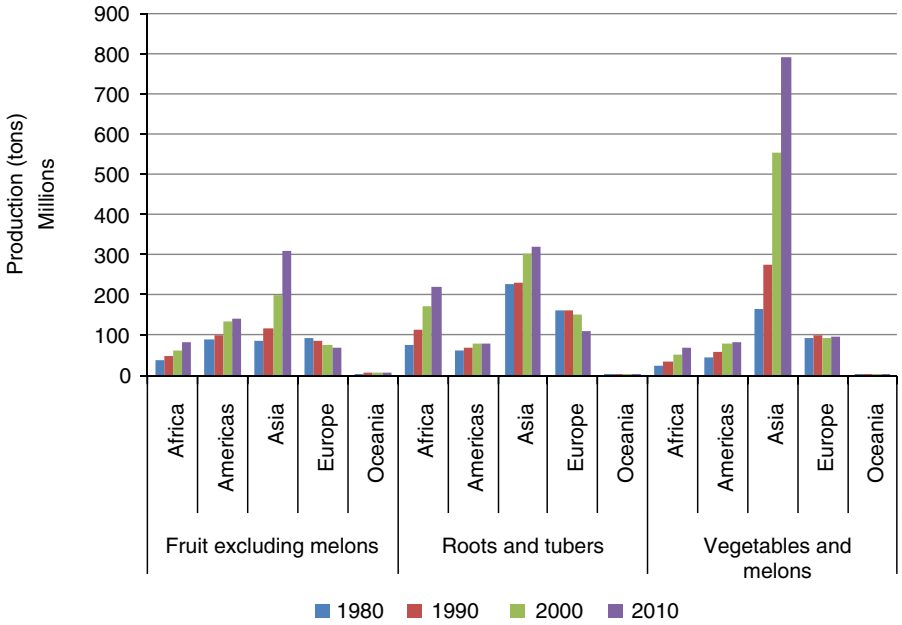

Figure 1 Horticultural production of fruits and vegetables from 1980 to 2010 from different regions of the world (FAOSTAT, 2012).

Projected Climatic Changes

Mean Climate Change

Global warming estimates and representative ranges have been documented in the Intergovernmental Panel on Climate Change (IPCC) Special Report on Emission Scenarios (Nakićenović and Swart, 2000). By 2030, assuming rapid population growth and a mix of future energy sources (a mid-range IPCC emission scenario), the globe is estimated to warm by an average of 0.9 °C (0.5–1.4 °C) (IPCC, 2007). Patterns of change for temperature and precipitation taken from simulations of 23 climate models were projected for 2030 under this A1B scenario (Watterson and Whetton, 2011; **Figure 2**). The models indicate that the Northern Hemisphere is expected to warm faster than the Southern Hemisphere and continental regions will warm at a faster rate than coastal regions.

A range of projections for rainfall change from among climate models indicate that some regions of the globe will likely get wetter and others drier (**Figure 2**), with regionally varying levels of model agreement, hence certainty (not shown in the figure, see IPCC, 2007). The pattern of rainfall change broadly shows subtropical regions have a drying trend whereas increasing rainfall is projected in some equatorial and high-latitude regions (IPCC, 2007; **Figure 2**).

Extreme Weather

Extreme weather and climate events such as frost, drought, heat waves, hail, cyclones, and floods all have the potential to impact severely on horticultural production. Under global warming, changes in the frequency, intensity, spatial extent, duration, and the timing of extreme weather is likely. It should be appreciated that some climate extremes (e.g., droughts) may be the result of a combination of weather events that are not extreme when considered independently (IPCC, 2012).

An increase in the frequency of extreme events has been observed already (Alexander *et al.*, 2006) and it is very likely that extreme heat events, heat waves, and heavy precipitation events will become more prevalent. Based on a range of climate models, tropical cyclones (typhoons and hurricanes) are projected to become more intense, with larger peak wind speeds and heavier precipitation associated with continual increases to tropical sea surface temperatures (IPCC, 2007).

Observed decreases in the number of cold days and nights (Alexander *et al.*, 2006) may point to a possible advantage of climate change for horticultural production, except in the case of winter chilling requirements. These observations in conjunction with projected warming of the climate (IPCC, 2007) may reduce the number of frost days, decreasing crop loss and damage from cold events.

Climate Change Impacts on Horticulture

Selection of favorable sites involves understanding the plant environment – physiology relationship in order to minimize deleterious impacts resulting from growing species in sub-optimal conditions (Schaffer and Andersen, 1994). With climate change, important environmental conditions for production will be modified. Interpretation of the potential effects of these changes is required to minimize adverse impacts through adaptation and take advantage of possible benefits.

Both negative and positive impacts on production are expected to transpire under future climate conditions. These impacts are dependent on the plant species, geographical region, and future changes to the spectrum of climatic variables that influence plant production. Generally, perennial crops will be more vulnerable than annuals to changes in the climate. Perennial crops are characterized by high investment permanent plantings often with long productive life spans, whereby measurable changes to climate will occur over the

Table 1 Ranking of major (fresh) horticultural production categories (tons produced) in different regions and globally

	Africa	*Americas*	*Asia*	*Europe*	*Oceania*	*World*
Fruit (fresh)						
1	Plantains	Oranges	Watermelons	Grapes	Grapes	Bananas

productive life of the plant. Some cultivars additionally have extended juvenile periods (early life phase dominated by vegetative growth), such as pecan (up to 10 years) (Thompson and Grauke, 2003). These long lead times to production increase vulnerability to future changes. Annual crops, however, can be modified more easily to incorporate different varieties or management strategies and they also produce on shorter timeframes.

Temperature Impacts on Growth, Yield, and Quality

Temperature is a key determinant in the successful production of horticultural products. With climate change, warmer temperatures may act to hasten developmental phases of plants. For annual crops such as lettuce (Pearson *et al.*, 1997), French bean (Wurr *et al.*, 2000), and tomato (Maltby, 1995), this may allow for more cropping cycles per year, resulting in increased production.

Changes of timing in winegrape ripening has been observed in Europe (Jones *et al.*, 2005; Le Roy Ladrie, 1988; Seguin and de Cortazar, 2005) and Australia (Petrie and Sadras, 2008). A recent study of 44 vineyard sites from 12 regions located in southern Australia reported a trend to earlier maturity of wine grapes in 43 of the blocks (Webb *et al.*, 2011; **Figure 3**). In the one site where an advance in ripening was not observed, Margaret River, the region had also not experienced

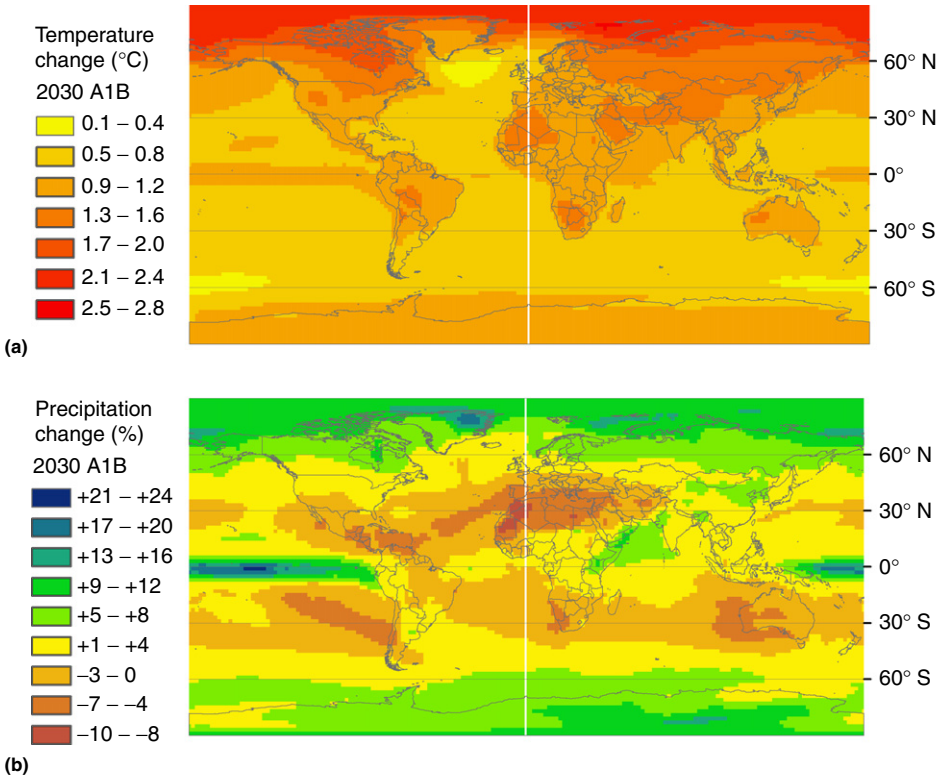

Figure 2 Projected annual temperature change (°C) (a), and annual rainfall change (%) (b) by 2030 (A1B emission scenario) as it varies spatially across the globe. Results depicted indicate the median of 23 CMIP3 climate models (Watterson and Whetton, 2011).

a warming growing, season for the period of observation. Over the more recent period, that is, 1993–2009 the average advance was 1.7 days per year, whereas for the period 1985–2009 the rate of advance was 0.8 days per year on average. With projected warming, ripening is anticipated to occur even earlier and in hotter climatic windows (Webb *et al.*, 2007b, 2012). Early ripening can have an adverse impact on wine quality with higher temperatures associated with altered balance of flavor and aroma compounds (Marais, 2001), hastening acid degradation (Liu *et al.*, 2006), and increasing the speed of sugar development (Sadras and Moran, 2012). Changes to wine styles and cultivar suitability are anticipated in the future (Webb *et al.*, 2013).

Many other crops across the globe have similarly recorded changes to phenophase timing in agreement with those expected from climate change (Rosenzweig *et al.*, 2008). For instance, the timing of apple flowering in France has been observed to advance by 2.6–3.0 days per decade in response to warming (Legave *et al.*, 2008). In contrast, observations in Australia are less pronounced with some apple growing regions recording a delay in flowering timing (1.4 days per decade) (Darbyshire *et al.*, 2013b). If observed advancements to flowering continue, interruptions to important production processes may transpire. For example, some crops require cross-pollinating varieties for fruit development (e.g., sweet cherries, pears, and apples). Asynchronous advancement of flowering between cross-pollinating varieties may cause misalignment of the flowering periods, potentially affecting pollination success, and, therefore, fruit set and yield. As well as tree cultivars losing synchronicity, pollination vectors may become climatically isolated from their food source, for example, butterflies and *Prunus* spp. (Doi *et al.*, 2008).

Many perennial deciduous fruit and nut trees require exposure to cool temperatures over winter to break dormancy and enter normal spring growth. Insufficient exposure to these winter chilling temperatures can lead to protracted and reduced bud break, poor pollination, abnormal fruit development, and small fruit sizes (Oukabli *et al.*, 2003; Petri and Leite, 2004; Saure, 1985; Voller, 1986; Maggs, 1975). Globally, it is expected that most temperate fruit and nut producing regions will face lower chill conditions in the future (Luedeling *et al.*, 2011). These chill conditions may drop below varietal threshold requirements leading to adverse production outcomes. Higher latitude regions are predicted to be minimally affected and in some circumstances accumulated exposure to chill is expected to increase (Luedeling *et al.*, 2011). Temperate growing regions may be significantly affected by declining winter chill, for example, Australia (Darbyshire *et al.*, 2013a).

Simulations of projected changes to pome fruit tree (e.g., apple and pear) flowering indicate that, depending on the cultivar selection, the physiological characteristics of the plant and expected climate change, flowering time may be delayed, advanced, or remain unchanged (Darbyshire *et al.*, 2013b). These different responses are the result of the opposing actions of delayed winter chill accumulation and acceleration of the time required to develop flowers (**Figure 4**). Exactly how a warming climate will affect the timing of budburst is not straightforward. For example, in a cool region (**Figure 4(a)**)

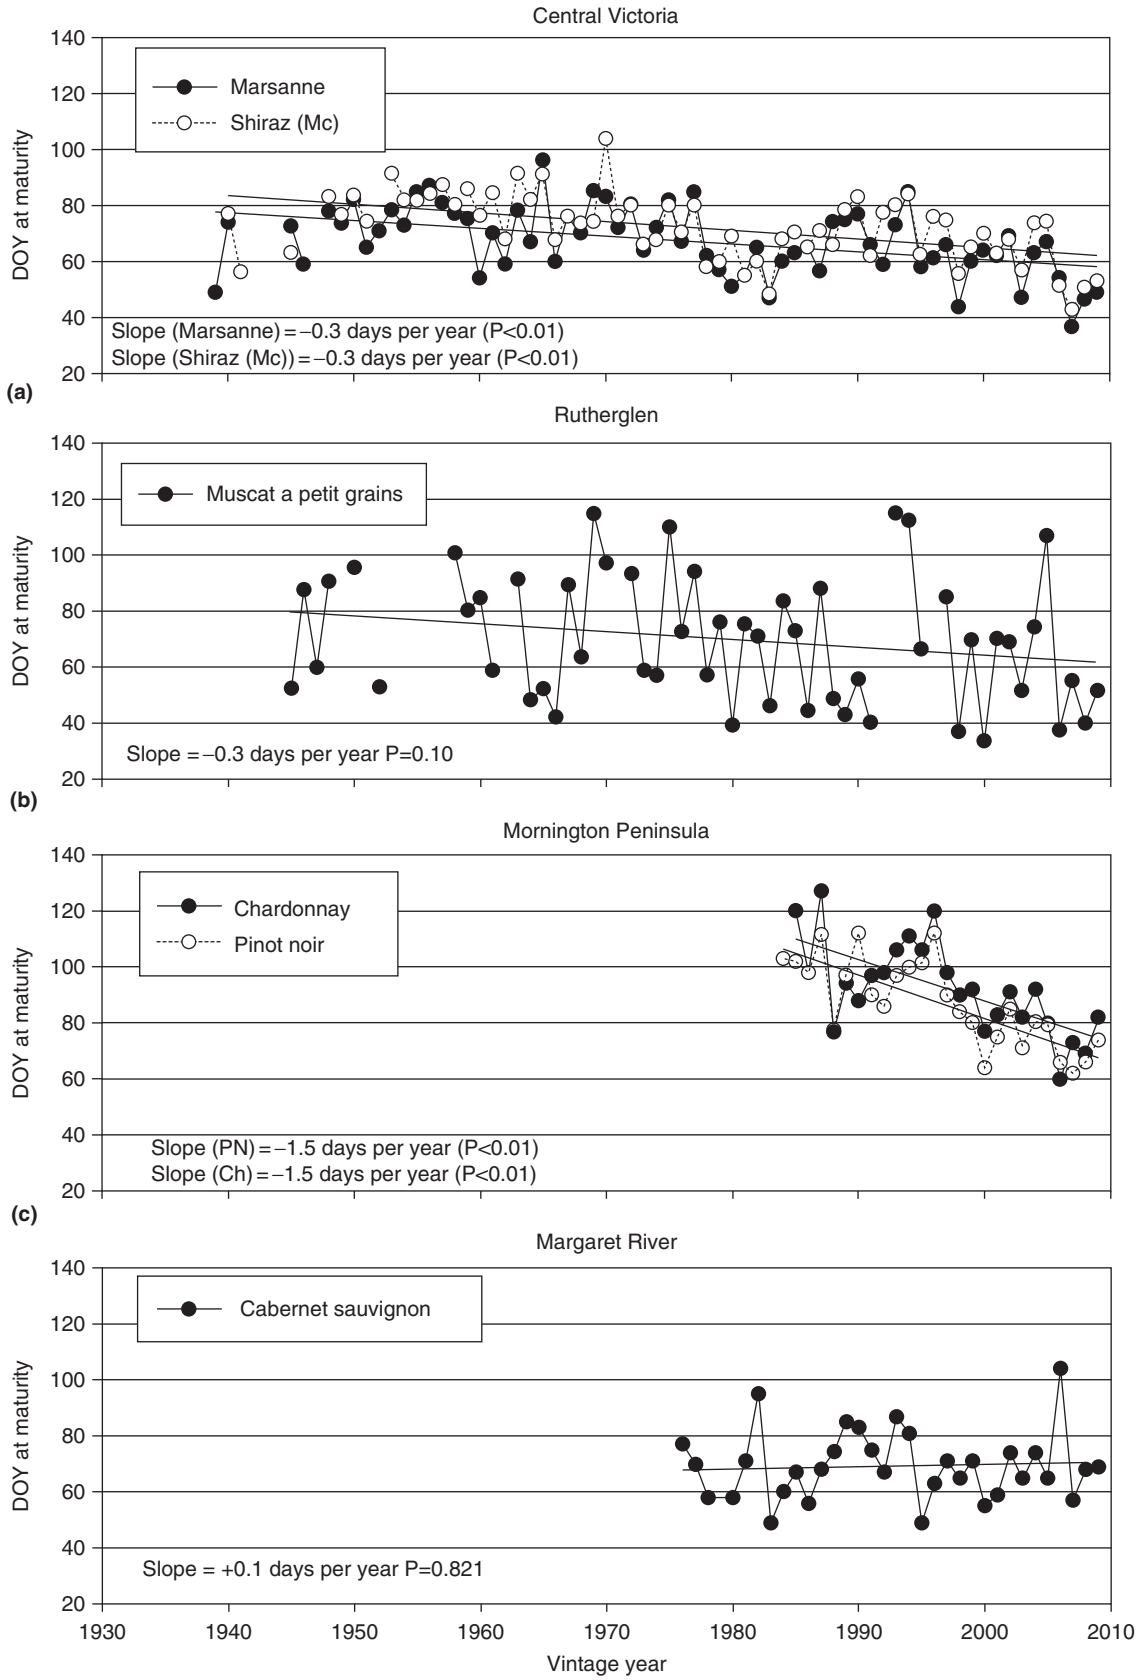

Figure 3 The observed day of year (DOY) at maturity recorded for six blocks from four regions (a) Central Victoria: Marsanne (1939–2009) (solid circles), Shiraz (Mc) (1940–2009) (open circles) and (b) Rutherglen: Muscat a Petit Grains (1945–2009) (c) Mornington Peninsula: Chardonnay (1985–2009) (solid circles) and Pinot Noir (1984–2009) (open circles), and (d) Margaret River: Cabernet Sauvignon (1973–2009). The best fit linear regression indicates the average trend in the maturity day (Webb *et al.*, 2011).

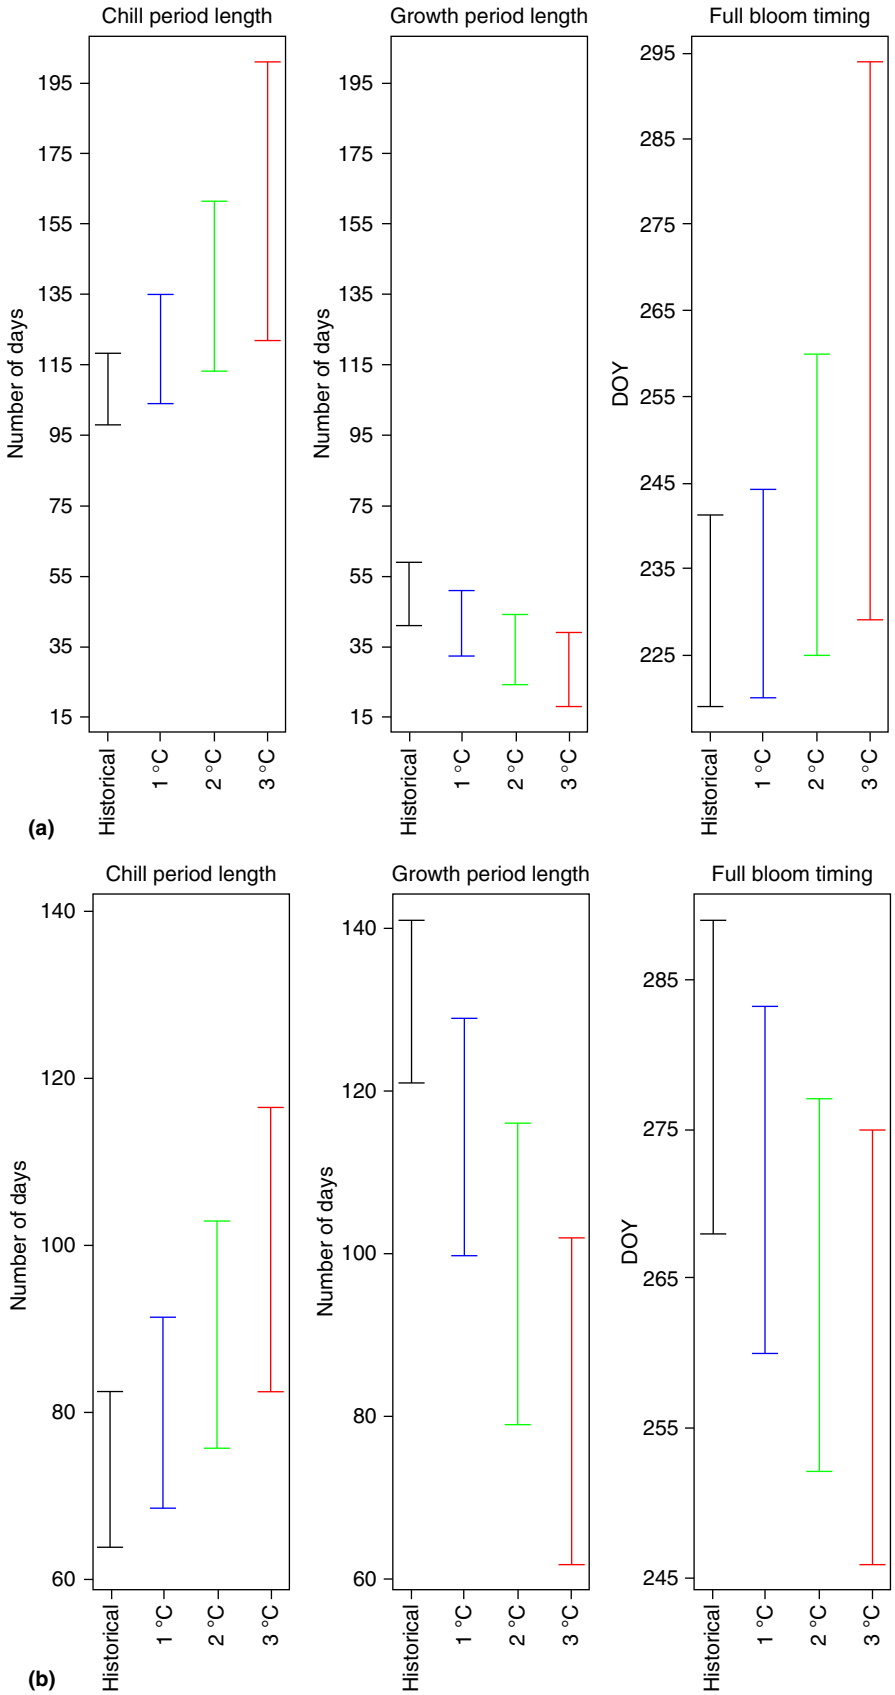

Figure 4 Alternate simulations for projected changes to pome fruit full bloom timing at (a) cooler and (b) warmer location. Projections are relative to +1, 2, and 3 °C increases to mean global temperatures. The relative influence of the chill and growth periods on expected flowering timing led different prediction of flowering delay or flowering advancement (unpublished data).

although chill is prolonged with a warming climate, the projected warmer spring still dominates the dormancy-breaking process, leading to earlier bloom time. In contrast, in a warmer region (**Figure 4(b)**), chill accumulation is already marginal in the current climate. With warming, chill is noticeably delayed and the limited influence of warming in spring does not compensate for this, leading to an overall delay in budburst. This regional variation in response has implications for future changes to frost incidence during the flowering period for apples (Darbyshire *et al.*, 2013c).

It should be appreciated that changes to the timing of flowering is yet to be fully understood from a physiological point of view, with greater research into phenology–temperature relationships, as well as development of models to represent these, required (Darbyshire, 2013).

The physiology of tropical crops may also be influenced by warmer winters. Temperatures between 11 and 14 °C are optimal for flower growth in lychee (Gao and Huang, 2004). Winter temperatures higher than this optimal may encourage vegetative over floral growth and thereby decrease the productive output of the plant (Chen, 2012).

Changes to springtime temperatures may also influence production with excessively warm temperatures during bloom or early fruit set known to induce abscission (premature fruit fall) in citrus fruit (Rosenzweig *et al.*, 1996), capsicum, and chilies (Murison, 1995), and adversely affect pollination of avocado (Schaffer *et al.*, 2002) and some tomato varieties (Sato *et al.*, 2000). High spring temperatures can cause reductions to peach yields (Lopez *et al.*, 2007), and modeled impacts have shown that future yields of almonds, table grapes, oranges, walnuts, and avocados are likely to be affected (Lobell *et al.*, 2006; Stöckle *et al.*, 2010). Berry collapse in table grapes (Tilbrook and Tyerman, 2008) has been associated with high temperature conditions during postberry set.

High-temperature impacts can be negative for quality and yield across many varieties. Reduced sugar content in products such as pea, strawberry, and melon produced under warmer nights is often attributed to increased night-time respiration. However, this effect may also be caused by high temperatures reducing the period over which fruit develops (Wien, 1997). An increase in maximum temperatures may negatively impact yield and quality of leafy crops such as lettuce and spinach (Titley, 2000). Bolting (premature formation of the seed head/flowers) is an example of a negative impact resulting from growing these crops in high temperature regimes (Dioguardi, 1995). The timing of elevated temperatures has been shown to reduce vitamin C levels in fruit production in woody perennials (Richardson *et al.*, 2004).

Production of anthocyanins (pigments responsible for the red, purple, and blue colors) for apple, pear, purple potato, pomegranate, legumes, and grapes is often related to commercial quality and the health advantages of foods (for a review, see Tsuda, 2012). The accumulation of anthocyanins is partly dependent on environmental conditions with cool minimum temperatures during maturation promoting production whereas high maximum temperatures act to destroy the compound (Lin-Wang *et al.*, 2011; Marais *et al.*, 2001; Steyn *et al.*, 2004; Xie *et al.*, 2012). As such, coloration may be degraded due to both higher minimum temperatures and higher maximum temperatures. Citrus fruit quality, with respect to both development of sugars and color, is also influenced by warmer temperatures, with a decrease in tree storage time and rind regreening increasing as temperatures rise (Rosenzweig *et al.*, 1996). The red color of ripening capsicums develops between 18 °C and 25 °C. But if temperatures rise above 27 °C during the ripening, a yellowish color results (Murison, 1995). Yellowing can also occur in tomatoes experiencing high temperatures when ripening (Maltby, 1995).

After harvest, many products including beans, melons, cherries, and strawberries require cooling so as to remove field heat quickly (Alique *et al.*, 2006; Coombs, 1995). With projected temperature rises, the costs and benefits of shifting harvest time to a cooler part of the day, or increasing refrigeration, will need to be assessed. Further, higher growing temperatures may negatively impact the shelf-life of lettuce (Rogers, 2007).

Benefits to horticultural production from increasing temperatures are also likely. For instance, mangoes grown in the subtropics can suffer from leaf yellowing when winter temperatures fall below 10 °C, due to photoinhibition of the photosynthetic apparatus (Sukhvibul *et al.*, 2000). This low temperature photoinhibition has also been reported for lychee and rambutan (Diczbalis and Menzel, 1998) and banana (Damasco *et al.*, 1997). In a warmer climate, cold-induced photoinhibition will be reduced and greater agronomic potential may exist in some areas currently considered to be marginal. Further, there may be benefits for Solanaceous vegetable crops (e.g., tomatoes and capsicum), which are currently seeded in heated glasshouses and transplanted into the field when the danger of frost has past (Peet and Wolfe, 2000). These crops may be directly seeded at locations where frost risk reduces, lowering production costs. Production of dried fruit, such as Thompson Seedless (sultana) and raisins, could also benefit as solar drying capacity increases as temperatures rise and humidity and rainfall decrease in regions with Mediterranean climates (Possingham, 2008).

Water Balance Impacts

Access to adequate water supply is a fundamental requirement for horticultural production. Generally, rain-fed systems are likely to be more vulnerable to future climate changes than irrigated crops. Nevertheless, irrigated horticulture may still face challenges for regions with predicted decreases to rainfall and increased evaporation leading to lower inflows into catchments, reducing the water available for irrigation (Cai *et al.*, 2009; Daccache *et al.*, 2011; Potter *et al.*, 2008). Similarly, reduced winter snow accumulation in colder regions may reduce stream flows due to lower snow melt run-off, with projections for Yakima basin in Washington State indicating such water shortages are likely to increase with future warming (Vano *et al.*, 2010). Compounding lower stream flows, competition of water resources from other sectors, such as for environmental, urban, or industry use, may further restrict water available to horticulturalists. In addition to changes in water availability and accessibility, crop water requirement will increase under warmer conditions. This puts greater pressure on water resources although increase in humidity and atmospheric CO_2 may counter the effects of elevated temperature on crop evapotranspiration (Snyder *et al.*, 2011).

Extreme Event Impacts

Changes in the frequency and severity of extreme events are likely to pose a substantial risk to future horticultural production. In a survey study of the effects of a heat wave event on grape vines in Australia, Webb *et al.* (2010) presented a range of impacts including stalled development, leaf burn, leaf drop, berry sunburn, and berry shrivel. The authors of the study suggested that the stalled or delayed sugar accumulation of up to 3 weeks was attributed to leaf damage during the heat wave (Kliewer and Dokoozlian, 2001), caused by heat-stress induced lack of water (Thorne *et al.*, 2006). The greatest delays occurred in the region where there was a cool lead-up to the heat wave, and the vines were not acclimatised to the heat. It is understood that consistently higher temperatures throughout the growing season have been shown to produce higher thermostability of photosynthesis functionality in grapevine leaves (Zsofi *et al.*, 2009). Through this same heat wave, citrus, apple, pear, and grapes were all adversely affected by direct radiation (**Figure 5**).

Future temperature projections indicate fewer frost days (IPCC, 2007) so it might be expected that horticulturists would experience less frost damage. However, if flowering occurs earlier, frost risk may not be reduced or stay the same (Darbyshire *et al.*, 2013c; Eccel *et al.*, 2009). In some regions, lower rainfall in spring and associated drier soils, fewer clouds, and lower dew points may even increase frost risk (Webb and Snyder, 2013). Furthermore, an increase in day-to-day climate variability may lessen any 'positive' impact of mean warming on reducing frost frequency (Rigby and Porporato, 2008). Changes to timing of frost events are important for horticultural production. For instance, the last observed frost day appears to have been delayed at Tatura, VIC, an important horticultural location in Australia (**Figure 6**). Such a delay will likely increase risk of damage to crops even if the overall number of frost events decline.

Increasing concentrations of carbon dioxide in the atmosphere have been found to render plants more susceptible to potential frost hazard (Woldendorp *et al.*, 2008). Nevertheless, for annual crops, a reduction in risk may be possible as planting/sowing dates can be managed.

Drought intensity and duration is projected to increase in some seasons and regions due to reduced precipitation or

Figure 5 Impact of direct radiation damage to (a) oranges, (b) apples, (c) pears, and (d) wine grapes during the 2009 summer heatwave in South-east Australia (pome fruit photos courtesy Malcom McCaskill, Vic DPI).

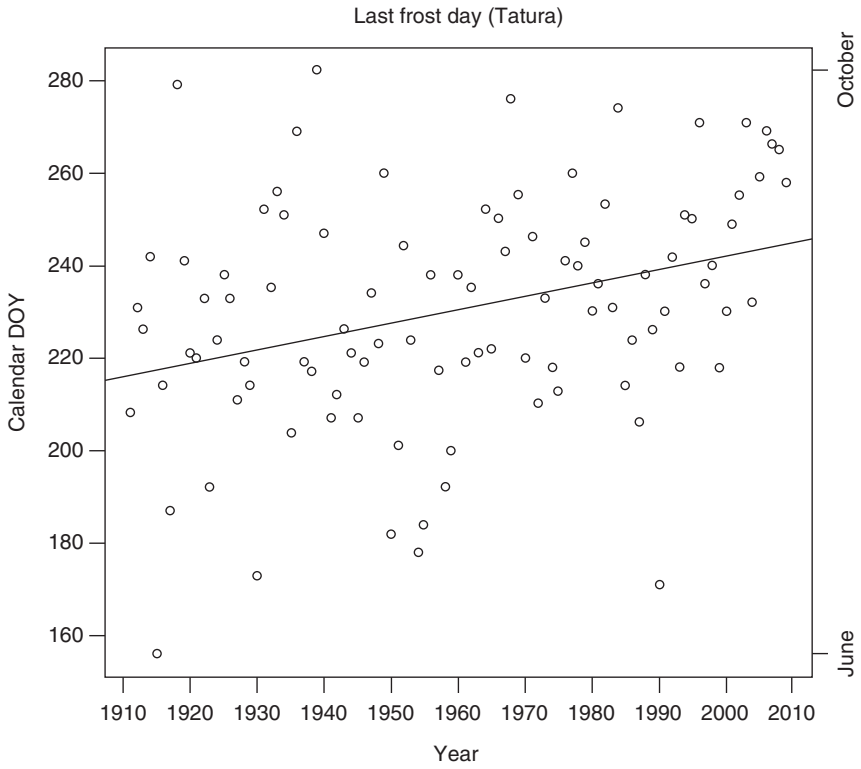

Figure 6 Observed day of year (DOY) relating to the last frost event (daily minimum temperature ≤ 0 °C) at Tatura, Australia (unpublished data).

increased evapotranspiration (IPCC, 2012). Economic impacts are often large with, for example, the 1999–2000 period drought in Iran reducing gross domestic product by 4.4% (Salami *et al.*, 2009).

In contrast to periods of drought, more extreme rainfall periods can also be problematic. Direct damage to the crop can result from high rainfall events. Splitting or cracking in cherry fruit arise from excess water uptake close to harvest. The degree of damage will vary with variety and seasonal effects (Measham *et al.*, 2009). Water logging of the root zone of most woody plants has a negative impact on physiology. Inadequate oxygen supply is the primary cause of damage (Flore, 1994). Flow on effects of excessive rainfall to management such as a delay to farm operations can disrupt production and add costs (Falloon and Betts, 2010). Further, with an increased incidence of extreme events (e.g., heat and flooding), the timing of spraying, harvest, pruning, and planting may be affected. Access to fungicides through flood events may be problematic if the recent Australian experience is any indication (Webb, 2011).

Australian region studies indicate a likely increase in the proportion of tropical cyclones in the more intense categories but a possible decrease in the overall frequency of cyclones (CSIRO and Australian Bureau of Meteorology, 2007). However, globally, there is low confidence in any observed long-term (i.e., 40 years or more) increases in tropical cyclone activity (i.e., intensity, frequency, and duration), after accounting for past changes in observing capabilities (IPCC, 2012). The magnitude of the impact cyclones can have is demonstrated by Severe Tropical Cyclone Larry (Australian Bureau of Meteorology, 2006), which crossed the Queensland coast of Australia in 2006. Devastating crop loss of AUS$300 million to the banana industry was initially caused, with a further AUS $150 million being required for replanting, renovating, and rebuilding after the cyclone (Leahy, 2006).

Hail can cause direct damage to crops and lead to large economic losses (Ogurtsov *et al.*, 2008). A recent study in the Netherlands showed that by 2050 annual hailstorm damage to outdoor farming could increase by between 25% and 50%, with considerably larger impacts on greenhouse horticulture in summer of more than 200% (Botzen *et al.*, 2010).

Climate change may also influence the characteristics of bushfires/wildfires (Lucas *et al.*, 2007). Smoke from bushfires (or controlled burning) can reduce the sensory characteristics of wine, leading to 'smoke taint' (Kennison *et al.*, 2008) and unsalable wine. Smoke taint due to bushfires cost Australian grape growers more than AUS$7.5 million during the 2003 and 2004 vintages (Whiting and Krstic, 2007). With the incidence of forest-fires projected to increase in the Mediterranean area (Moriondo *et al.*, 2006), a region with many vineyard plantings, the risk of smoke taint is likely to increase.

Human factors need to be considered when discussing impacts of climate change on horticulture. Direct impacts of climate change include increasing heat stress levels of workers. Where workforces are likely to be exposed to more extreme conditions, changes to current practices may need to be undertaken to avoid potential negative human health outcomes (Kjellstrom *et al.*, 2009). Other impacts of drought on the community can be subtle and difficult to economically quantify although of significant social concern. In Australia, research has indicated that during periods of drought rates of suicide in males in rural areas notably increases (Hanigan

et al., 2012). Aspects of social activities can also be affected, further impacting communities. For example, a recent extended drought in Australia reduced access to sporting fields occurred as turf could not survive (Sport and Recreation Victoria, 2007).

Pest, Disease, and Weed Impacts

Elevated temperatures may increase pest and disease pressure due to higher populations caused by shorter life cycles and decreases to generation times (Aurambout *et al.*, 2006). Conversely, other factors such as lower rainfall and humidity may reduce disease pressure (Coakley *et al.*, 1999). Increased survival of pests that normally do not withstand cold winters, for example, the cabbage moth (*Phitella xylostella*) (Deuter, 1989), is of some concern in a warmer climate. Disease threat may also increase, as in the case of citrus canker, where warmer winter temperatures would support a continuous life cycle in subtropical and temperate regions and potentially favor establishment in regions outside its historic range (Aurambout *et al.*, 2006). A 1.0 °C rise in temperature is expected to dramatically increase the cost of controlling the Queensland fruit fly in Australia without accounting for any increased risk to current fly-free zones (Sutherst *et al.*, 2000).

The range and severity of Phoma stem canker (blackleg, *Leptosphaeria maculans*), an internationally important disease of wild and cultivated brassicas, may increase with projected climate change (Evans *et al.*, 2008). Models also predict an increase in severity of downy mildew (*Plasmopara viticola)* epidemics on grapes in an important Italian wine-producing region near Turin in 2030, 2050, and 2080 (Salinari *et al.*, 2006).

It is likely that anywhere where rainfall or humidity are projected to increase, the incidence of infections with fungal pathogen will increase (Magarey *et al.*, 1994; Webb, 2006). An increase in the frequency of extreme rainfall events, especially in combination with higher temperatures, may also lead to conditions that favor root-invading fungus like *Phytophthora cinnamomi*, which affects avocado (Howden *et al.*, 2005). Wet soils may predispose crops to rot development, whereas dry and warm conditions favor insect population growth and viral vector epidemics (Rosenzweig *et al.*, 2001).

Temperature changes, altered wind patterns, or flooding may allow tropical and frost-tolerant weed species to move into temperate regions. Competitiveness both between different weed species and between weeds and crop species may be altered (Fuhrer, 2003). Changes to weed seasonal survival can interact with pest pressure, with persistence of weed hosts for crop pests prevailing through winter, increasing the ability of pests (e.g., the Silverleaf Whitefly) to overwinter (known as a 'green bridge') (Aurambout *et al.*, 2006).

Finally, the direct effect of elevated CO_2 concentrations may also influence pest and disease pressure. High CO_2 concentrations can change host morphology and phenology, pest fecundity and life cycle, and plant disease epidemiology (Chakroborty, 2004). The confluence of changes to climate variables, host physiology, and pest and disease characteristics will dictate changes to plant susceptibility under climate change conditions.

Impacts from Changes to Carbon Dioxide

Direct impacts from changes to CO_2 concentrations may also influence future production of horticultural products. Higher concentrations of CO_2 may improve plant water use efficiency (Grant *et al.*, 2004; Morgan *et al.*, 2004) and reduce stomatal conductance. This reduced conductance could lower transpiration rates assuming the smaller aperture does not result in a very large increase in leaf temperature. Whether this affects water use efficiency of the whole plant depends on whether the leaf area increases, caused by the increased growth in enriched carbon dioxide environments, counteracts the effect of reduced stomatal conductance (Drake *et al.*, 1997; Rosenberg *et al.*, 1990).

For C3 crops, research suggests that elevated CO_2 may have many positive effects; including yield stimulation, improved resource-use efficiency, more successful competition with C4 weeds, reduced ozone toxicity, and in some cases better pest and disease resistance (Fuhrer, 2003). Across all horticultural species, the effects of elevated CO_2 on plant growth and yield will depend on photosynthetic pathway, species, growth stage, and management regime and its implications for water and nitrogen applications (Easterling *et al.*, 2007). Thus, it is likely that horticultural crop responses vary. Wurr et al. (2000) found a null response of French bean to CO_2 enrichment, whereas positive effects have been reported for onion (Daymond *et al.*, 1997), beetroot and carrots (Wurr *et al.*, 1998), avocado (Schaffer *et al.*, 2002), citrus (Rosenzweig *et al.*, 1996), and banana (Schaffer *et al.*, 1996).

As well as assessing the implications of these crop-specific CO_2 enrichment effects, interactions with related temperature and water supply changes will be imperative. These changes will modify, and often limit, direct CO_2 effects on plant growth (Easterling *et al.*, 2007). For instance, with lettuce, increasing CO_2 should increase yield, but this will be partially offset by warmer temperatures (Pearson *et al.*, 1997). Positive effects of CO_2 on potato crop growth counteracted the negative effects of warmer temperatures depending on the initial temperature regime (Miglietta *et al.*, 2000). In contrast, Rosenzweig *et al.* (1996) found minimal compensating effect of CO_2 on potato yields. Wurr *et al.* (1998) found carrots had a temperature optimum of approximately 15.8 °C for maximum responsiveness to CO_2 enrichment.

The quality of products may also be influenced under a CO_2-enriched atmosphere. Plant responses to elevated atmospheric CO_2 may increase the carbon to nitrogen ratios in plant tissue (Drake *et al.*, 1997; Morison and Lawlor, 1999). This can reduce the nutritional value of some vegetables to human consumers. In stating this, however, a review of many free air CO_2 enrichment studies has reported that this effect is small (Ainsworth and Long, 2005).

Horticultural Adaptation to Climate Change

Site Selection

Site selection for horticultural production is a practice critical to crop success even in a stable climate. Temperature, the dominant factor that determines where and when horticultural

crops are grown, has a significant influence on crop performance (i.e., time to harvest, product quality, and, to a lesser extent, yield). In a warmer future climate, this practice of carefully selecting appropriate sites for annual crops will continue. However, when selecting sites for perennial species it is imminently more important and urgent to consider the changing climate. This is because some of these crops (e.g., fruit trees and grape vines) have an average life of more than 30 years. Within that time-frame global average warming of at least 1 °C is anticipated (Rahmstorf *et al.*, 2007), and crops planted today are expected to remain productive.

By selecting more elevated sites, or avoiding north-westerly aspects in the Southern Hemisphere and south-westerly aspects in the Northern Hemisphere, horticultural potential can be extended where regions may otherwise become too warm. Ultimately, if climate warming increases to a level whereby the region becomes too hot for the particular crop, pole-ward shifting of horticultural zones will enable production to continue, with increasing suitability of currently cold-marginal regions (Olesen and Bindi, 2002). For example, horticulture production is currently limited by winter temperatures and late spring frost in northern European regions like Scandinavia and Siberia (Dehnen-Schmutz *et al.*, 2010) and the UK (Daccache *et al.*, 2011). Further, an assessment of the productive range of apples in Finland for the year 2040 found that land suitable for production will increase northward as will the range of varieties available for cultivation (Kaukoranta *et al.*, 2010).

Mapping of threshold temperatures and other relevant aspects of the climate for a range of future climate regimes can expose risky, or less-risky, areas in which to plant crops. With a potential reduction of frost-prone areas under climate change, the area suitable for growing tropical and subtropical crops is projected to expand, such as for olives (Olesen and Bindi, 2002), citrus, avocados, and bananas in the Mediterranean region of Europe (Houerou et al. 1992) and for avocados and pecan nuts in Southern Africa (Schulze and Kunz 1995).

Changing average rainfall conditions may increase or reduce suitability for growing certain crops. Note that where crops are irrigated the catchment may be remote from the production area. In these cases information regarding projected rainfall over the catchment region will be essential for planning purposes (Chiew et al., 2009).

A global-scale increase in extreme rainfall may mean increasing risk of floods or erosion (IPCC, 2012). Impacts are complex and influenced by localized factors, but avoiding low-lying sites and considered planting of erosion-prone slopes may help avoid some of the potential impacts from these precipitation events. In tropical regions, although the number of cyclones is projected to reduce in future, the intensity of these may increase, so selecting sites to avoid cyclone hazard, for example, away from the coast, may be advisable.

Crop Management

The timing of management activities, such as planting, fertilizing, and irrigation can be adjusted in response to climate shifts (Krug, 1997). Because climate change is expected to reduce the duration from sowing to harvest for some annual crops there can be consequent reductions in yield (Olesen *et al.*, 1993). These yield decreases may be compensated by sowing annual crops earlier. Where crops mature more rapidly, it may be necessary to plant smaller areas of crop more frequently in an attempt to reduce market supply fluctuations (e.g., for cauliflower) (Olesen and Grevsen, 1993). In some areas, autumn soil temperatures could become too high for good germination of celery so planting later in the season can be an option (Peet and Wolfe, 2000). For potatoes, however, planting later in the season to avoid very hot temperatures may be compromised by the shorter day lengths later in the year, which have a negative impact on yield (Rosenzweig *et al.*, 1996). Thus, any planned change in sowing needs to be accompanied by considerations of day length requirements. As the timing of winegrape harvests has been linked to soil–moisture status, crop load, and temperature (Webb *et al.*, 2012), water management or crop-load manipulation could be used to manage undesirable shifts in timing under climate warming.

Given chilling levels are projected to reduce in temperate regions (Luedeling *et al.*, 2011), managing variable and protracted bloom of pome and stone fruit and nut trees may be necessary (Saure, 1985). For example, pesticides with longer residual action may be required to protect the crop if the flowering period is substantially lengthened. Application of hydrogen cyanamide, to promote budburst as an adaptation option for inadequate chilling, is becoming more common in perennial fruit-growing operations (e.g., table grapes; George and Nissen, 1990), though concerns regarding risks due to human exposure have been reported (Schep *et al.*, 2009). Evaporative cooling by water sprinkling (Nir *et al.*, 1988; Erez and Couvillon, 1983) can also be used to lower winter temperatures and thereby increase chill accumulation. However, this adaptive strategy needs to be balanced against water supply and security. Rootstock selection is a promising area for future research to adapt to lower chill conditions yet retain the same variety mix. Finetto (2004) considered the influence of rootstock on chilling requirements of Golden Delicious apple. Rootstock was found to be important with plants on M-11 rootstock appearing to require less 'chill' than those on either M-26 or M-27.

Extreme rainfall is likely to increase in frequency (IPCC, 2012) and consequently flooding may also occur in some regions. Schultz (2000) explains that in Europe, shifts in precipitation patterns may necessitate introduction of cover crops between vine rows in order to minimize soil erosion. Such measures could include the planting of interrow groundcover using 'drought-tolerant' grass and legume species (Pardini *et al.*, 2002). Plastic shelters are another way used to minimize damage from untimely or extreme rainfall events reducing berry splitting and berry drop in table grape production (Possingham, 2008).

Diverse management approaches enacted before and during a severe heat wave in Australia in 2009 have been documented (Webb *et al.*, 2010). Variations in management of water application, canopy cover, row orientation, and phenological stage were found to affect the level of impact. For example, water application before the heat wave was found to be useful in ameliorating the level of impact (**Figure 7**). If the leaf canopy protected the grape bunches from radiation,

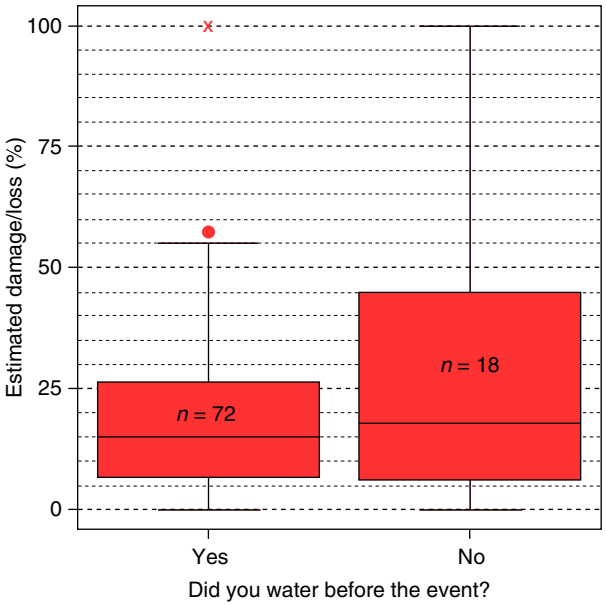

Figure 7 Survey results showing estimated damage/loss (%) of individual growers' winegrape crop in relation to timing of irrigation application with regard to the 2009 summer heatwave in south-eastern Australia (Webb *et al.*, 2010).

reduced fruit damage was also reported (Webb *et al.*, 2010). In the case of perennial tree crops, consideration of canopy structure could also be scored for useful traits such as natural self-shading ability. In some cases, however, increased canopy management in an enriched CO_2 environment may need to be addressed if CO_2 stimulates vegetative growth causing intra-canopy shading.

Hail netting has been found to be particularly suited to high-yielding, intensive apple orchard systems in Australia to reduce fruit sunburn, improve color and skin finish, and eliminate bird damage (Middleton and McWaters, 2002). Commercial kaolin-based coatings (also used as a pest repellent) can also be used to reduce sunburn (Thomas *et al.*, 2004). Further, evaporative cooling from overtree sprinklers can lower fruit temperature (**Figure 8**), reduce sunburn (Parchomchuk and Meheriuk, 1996), and improve color in apple (Thomaia *et al.*, 1998).

Lower levels of management and cost saving may also result from climate warming. For instance, many horticultural crops are grown in glasshouses to protect against unfavorable weather. In higher latitude climates these are often artificially heated adding cost to production. With a warming climate, a reduced need for heating will lower energy costs to the producers (Storck, 1978) and improve returns.

Varietal Selection and Crop Breeding

Every winegrape variety has specific genetically determined phenology (McIntyre *et al.*, 1982), which results in very different times of harvest (Gladstones, 1992; Kerridge and Antcliff, 1996). Matching of the phenology of the different varieties to a particular climate is a fundamental aim for every vineyard manager (Jones and Davis, 2000). The impact of climate change on varietal suitability in viticulture sites in European (Kenny and Harrison, 1992; Schultz, 2000) and Australian regions (Webb *et al.*, 2007a) have been examined. A global intercomparison of projected climate changes offers winegrowing practitioners a chance to assess the spatial variability of the changing climate and provides analog future climates for comparison (Webb *et al.*, 2013). As such, variety selection for replanting can be made in view of phenology traits that will be anticipated in future climates.

Approaches to matching varieties to climate also exist for annual crop production. In some cases, long season varieties may be more suited to a future climate than short season varieties (e.g., onion) as the hastened progression through phenological stages can be somewhat negated (Daymond *et al.*, 1997). One advantage of this is that ripening in a later and possibly cooler part of the season could reduce the risk of potential curing problems (Salvestrin, 1995). Alternatively, double-cropping could be practiced using shorter season varieties at some sites with some crops (Meza *et al.*, 2008), though this has implications for increased water use.

Crop or cultivar selection and planting dates can be changed to either suppress flower initiation, in the case of celery, onion, or cabbage, or delay flowering, in the case of broccoli and cauliflower (Coombs, 1995). Crops with extended flowering periods like peas and pumpkin are less sensitive to periods of heat stress compared with those that have more tightly determined flowering times (e.g., cauliflower and broccoli) (Peet and Wolfe, 2000).

Breeding for improved tolerance to heat and enhanced water use efficiency, with consideration of the interactive effect of increasing concentrations of CO_2 on physiology, provides an adaptation option for crops growing in subtropical regions, where a warming and likely drying climate is projected. There exists great potential to enhance the adaptive capacity of grapevines through conventional breeding or genetic manipulation. With a large pool of genetic variants (both varieties and clones) (Thomas and Van Heeswijck, 2004), and 500 million bases of the *Vitis vinifera* genome now sequenced (Velasco *et al.*, 2007), the research community is in a strong position to address the future and continuing challenges the changing climate. Breeding varieties more adapted to high temperatures can also reduce quality concerns with regard to lettuce (Rogers, 2007) and yield concerns with peas (Olesen *et al.*, 1993) and potatoes (Manrique and Bartholomew, 1991).

Stone-fruit varieties are defined by the chill requirements of the tree (Saure, 1985). To combat this restrictive feature, low chill stone-fruit are being bred for subtropical areas where very low winter chilling is experienced (Topp *et al.*, 2008; Topp and Sherman, 2000; Wilk, 2005). These varieties can also be utilized in areas expected to experience lower winter chill conditions.

Water Management

In many regions of the world, horticultural production occurs where the water requirement of crops is far higher than that provided by effective rainfall. In these places irrigation has been widely adopted to maximize yield and quality, giving more surety of harvest dates and also facilitating marketing

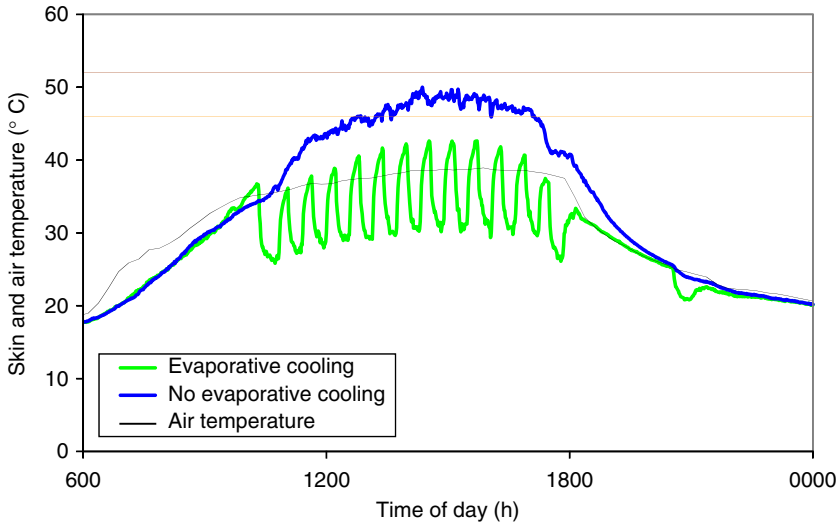

Figure 8 The effects of evaporative cooling on skin temperature of fruit exposed to direct sunlight in a commercial Royal Gala apple orchard in southern Australia. Evaporative cooling was imposed by applying water through permanent overtree microjets. Water was applied for 20 min and then turned off for 15 min. The horizontal lines represent thresholds for sunburn browning and sunburn necrosis (unpublished data).

plans of growers. With projected drying in subtropical regions, irrigators may need to reassess their irrigation strategies. In the United Kingdom, for example, modeling studies indicate that by the 2050s the capacity of existing irrigation schemes would fail to meet future irrigation demands for potato production in approximately 50% of years (Daccache *et al.*, 2011).

Options to reduce on-farm water needs include investing in improved irrigation management to match crop water requirement, and irrigation equipment to increase application uniformity and efficiency (Daccache *et al.*, 2011). Estimating crop water requirement from weather data with feedback from measurements of soil moisture, deep drainage, and crop water stress will improve irrigation management. Many vegetable growers use drip irrigation technologies, which provide a significant improvement to water use efficiencies when compared to furrow or sprinkler irrigation systems (Fereres *et al.*, 2003). The best irrigation practice to implement, however, can vary with soil type and crop morphology (Al-Jamal *et al.*, 2001). Deficit irrigation strategies like partial root-zone drying (Zegbe-Domíngueza *et al.*, 2003) and regulated deficit irrigation (Kriedemann and Goodwin, 2003) are strategies that could be explored more rigorously in some horticultural cropping regimes. Modifying soil structure to improve soil moisture retention (Bronick and Lal, 2005) or mulching the soil surface with organic matter can reduce the loss of water through evaporation (Tindall *et al.*, 1991). Night-time watering may result in reduced evapotranspiration losses. Applying saline water strategically may assist some growers to cope with severely reduced access to water in drought situations, though effects on soil structure will need to be considered (Clark, 2004). Cost and efficiency of distribution, holding dams, dam evaporation, and water quality maintenance will also need to be reviewed (Van Dijk *et al.*, 2006).

Drought is a common occurrence in the United States, (14% of the country experiences severe or extreme drought at any one time). So a national database of drought impacts and the economic losses associated with these impacts is being developed and is anticipated to provide comprehensive and timely information for researchers, planners, policy makers, and the general public (Ding *et al.*, 2011).

Increased use of reclaimed wastewater for horticultural enterprises can be considered. A summary of the major impediments to the use of reclaimed water by the Australian horticultural industry has been compiled (Hamilton *et al.*, 2005). Insufficient knowledge of impacts on market acceptance and of food safety issues, inadequate understanding of consumer perceptions and uncertainty about pricing of reclaimed water were raised as some of the potential issues that need to be resolved.

In some regions rainfall may increase on average in future. Disadvantages of increases in rainfall may be an increase in the need for plant protection from diseases, the risk of nutrient leaching, and the turnover of soil organic matter (Olesen and Bindi, 2002). More vigilance in disease management, as well as monitoring soil fertility will offer some adaptive potential, though both these options will add to the cost of production.

Whether elevated atmospheric CO_2 concentration reduces transpiration depends on the effects on leaf area index as well as stomatal conductance (Drake *et al.*, 1997), interactions between stomatal conductance, and increased vapor pressure deficit. Although increases in plant water use may result from possible increases in leaf area index, balancing this and possible reduced water use due to decreased stomatal conductance will need to be better understood to determine future water requirements for crops.

Weeds, Pests, and Diseases

Management of horticultural pests using pesticides, cultural practices, and biological control methods in relation to current climate variability depends on effective monitoring and predictive systems (e.g., Hetherington, 2005), varies with crop type, and is undertaken as a matter of course by horticulturists.

Certain existing preventive plant protection measures, such as use of a diversity of crop species in cropping systems, adjustment of sowing or planting dates, use of crop cultivars with superior resistance or tolerance to diseases and abiotic stress, use of reliable tools to forecast disease epidemics, application of integrated pest management strategies, and effective quarantine systems, may become particularly important in the future (Juroszek and von Tiedemann, 2011).

Under climate change, disease-assessment models should account for projected changes to overwintering of a wide range of insect pests and plant diseases and changes in the timing and severity of pest outbreaks. To date, the most common bioclimatic models used to predict potential range shift of species under climate change are 'CLIMEX' and 'BIOCLIM' (Aurambout *et al.*, 2006). Geographically sensitive models that use projected climate information focused on the use of biopesticides and natural enemies can be constructed to improve pest control. CO_2 effects on disease and hosts have to be considered when addressing future disease risks.

There is a clear requirement for consistently utilizing, adapting, and improving crop protection strategies and tools and enhancing the relevant knowledge base (Juroszek and von Tiedemann, 2011). Improved understanding of the drivers of disease cycles, epidemic development, and host responses will continue to be a fundamental prerequisite to enable farmers and advisors to predict and manage diseases under changing local conditions (Chakroborty, 2004).

Integrating Knowledge

Rain, or the threat of rain, may cause growers to pick early to reduce risk of disease (Jackson and Lombard, 1993). Short-term forecasting of extreme rainfall events close to harvest will become crucial given the projected increase in these events. Farmers can incorporate knowledge of seasonal forecasts, informed by improved information regarding patterns of regional climate drivers (e.g., El Niño-Southern Oscillation; Meinke and Stone, 2005). However, to benefit from seasonal climate forecasts, the decision capacity of the smallholder farmers needs to be improved and greater emphasis should be placed on farmer involvement and a demand-driven participatory approach (Selvaraju *et al.*, 2004).

Consumer Behavior

Availability of most horticultural crops (e.g., strawberries) tends to vary throughout the year and may be reduced in some seasons due to production difficulties caused by effects of higher temperatures, droughts, or other climatic events. In these cases consumers can pay higher prices to growers or pay more for an imported product (if available). In Australia, banana prices increased dramatically after Severe Tropical Cyclone Larry devastated the crop in 2006 (Clements and Maesepp, 2011). Color or nutrition levels of produce could be impacted by climate change, with some of the possible esthetic impacts identified being regreening of oranges, and yellowing of tomatoes and capsicums. Ongoing marketing programs are increasing consumer awareness of new and varied alternative produce.

Conclusion

The effects of climate change on crop quality will vary. The magnitude and extent of these impacts will be governed by the present climate of the region, the rate of projected change of climate and crop type. Management inputs available to ameliorate any adverse climatic impacts will be determined by the value of the crop and grower capacity. Because overall vulnerability will be crop- and site-specific, it is difficult to determine this for the horticulture industry as a whole, especially at a global scale.

Adapting to a changing climate may occur autonomously. For instance, farm managers currently adjust to gradually increasing temperatures by modifying timing of planting on a year-by-year basis. In some instances management may become easier, for example, frost avoidance mechanisms may not need to be implemented. Glasshouses may not require as much heating, though cooling requirements may be increased. However, planned adaptation will also be needed, particularly for high value, long-lasting permanent perennial crops (e.g., apples) with the associated infrastructure.

A focus on conventional breeding programs and biotechnology, once some of the potential vulnerabilities of horticultural crops have been identified, can build resilient cultivars that are more suited to future climates, for example, drought-tolerant cultivars. Considering the impacts of rising CO_2 on crops (and the interaction of CO_2 with increased temperature) would assist this endeavor.

Seasonal forecasts can be utilized to address interannual climate variability to enable effective use of resources (e.g., labor and planting material). As knowledge of climate systems improves, these forecasts should become more accurate and sophisticated and could include considerations of climate change trends.

Validation of climate indices that determine locations of current horticultural enterprises can be modeled relatively quickly so that predictions of potentially suitable crops for each region, or potentially suitable sites for particular crops, can be assessed. Risks associated with climate extremes can be assessed at the same time as suitable macroclimates and mesoclimates are being evaluated. Substantial benefits can be achieved if damaging temperature threshold events can be avoided in future.

Similarly, calculating the risks associated with changes to water availability may alleviate any adverse impacts with regard to allocating water to various agricultural sectors in the future, or in avoiding flood-prone areas. It will be possible to assess the water requirements for horticultural crops more accurately if the effect of rising CO_2 on crop water use is better understood. It will remain necessary to continue improvements in irrigation technology.

After identifying relevant, crop-specific, climatic thresholds, it will be possible to estimate whether climate change will increase or decrease the risks of growing crops in particular geographic locations. Some new regions may be identified as becoming more suitable for horticultural production, whereas others may become less suitable. An increase in production from subtropical and tropical regions could see new products being introduced, or a changed accessibility of produce. This

change will most likely be gradual and marketing strategies will need to adjust accordingly.

Glossary

Anthropogenic Caused or influenced by humans.
Aquifers An underground layer of permeable rock, sediment (usually sand or gravel), or soil that yields water.
Forward genetics Comprise of genetics techniques that aims to identify genes/mutations that produce a certain phenotype.
Genebanks Type of biorepository which preserves the genetic material. In plants, this could be by freezing cuts from the plant or stocking the seeds.
Genetic engineering Direct manipulation of the genes in an organism, with the intent of making that organism better, using biotechnology.
Glaciers A huge mass of ice slowly flowing over a land mass, formed from compacted snow in an area where snow accumulation exceeds melting and sublimation.
Ice sheets Layer of ice covering extensive regions of the world, notably Antarctica and Greenland.
Marker-assisted selection A process whereby a marker (morphological, biochemical, or one based on deoxyribonucleic acid (DNA)/ribonucleic acid (RNA) variation) is used for indirect selection of a genetic determinant or determinants of a trait of interest (e.g., productivity, disease resistance, abiotic stress tolerance, and quality).
Near-isogenic lines A term used in genetics and is defined as lines of genetic codes that are identical except for differences at a few specific locations or genetic loci.
Reverse genetics An approach to discover the function of a gene by analyzing the phenotypic effects of specific gene sequences obtained by DNA sequencing.

Climate Change

Climate changes are occurring and the discussions on their impact are rising. Climate changes are already providing significant challenges to natural systems. The discussion on the consequences of climate changes concerns different knowledge areas. Most of the observed increases in global average temperatures since the mid-twentieth century are very likely due to the observed increase in anthropogenic greenhouse gas (GHG) concentrations. The Fourth Assessment Report of the Intergovernmental Panel on Climate Change (IPCC, 2007) indicates that the warming of the climate system is unequivocal, as it is now evident from observations of increases in global average air and ocean temperatures, widespread melting of snow and ice, and rising global average sea level. Significant changes in physical and biological systems have already occurred on all continents and in most oceans, and most of these changes are in the direction expected with warming temperature (Rosenzweig *et al.*, 2008). Global climate change is predicted to lead to extreme temperatures and severe drought in some parts of the world, whereas other parts will suffer from heavy storms and periodic flooding (Marshall *et al.*, 2012).

Estimates of changes in the global temperature are still uncertain. For the future, best estimates of temperature increases are in the range of 1.8–4 °C in 2090–99 relative to 1980–99, depending on the scenario of future GHG emissions that is used to drive the climate models (IPCC, 2007). Nevertheless, however low they may be, the consequences will be felt by all humanity to a greater or lesser degree. The most relevant fact is that most of the effects of these changes will affect developing countries (Lobell *et al.*, 2008).

There is a broad scientific agreement that the climate conditions are being changed on a global scale by human activities. Burning of fossil fuels, deforestation, and a variety of agricultural practices and industrial processes are rapidly increasing the atmospheric concentrations of CO_2 and other GHGs (IPCC, 2007). Projections to the year 2100 indicate that CO_2 emissions are expected to increase by 400% and CO_2 atmospheric concentration is expected to increase by 100% (Cline, 2007). Some studies have predicted increasingly severe future impacts with potentially high extinction rates in natural ecosystems around the world, and also, provided strong evidence of ongoing dramatic changes in the Earth's climate system. Among them, the long-term temperature records from ice sheets, glaciers, lake sediments, corals, tree rings, and historical documents demonstrate that every decade in the late twentieth century has been warmer than the preceding decades (Williams *et al.*, 2003; Thomas *et al.*, 2004; Hansen *et al.*, 2012; Jones *et al.*, 2009).

The most recent 50 years likely have been the warmest worldwide in at least the last 1300 years (IPCC, 2007), and 10 of the 11 warmest years on record have occurred since 2001 (Hansen *et al.*, 2012). Observations since 1961 show that at depths of at least 3000 m, the average temperature of the global ocean has increased; this deep storage of heat together with the higher heat capacity of water is causing the ocean surface to warm more slowly than the land surface (IPCC, 2007). Changes in snow, ice, and frozen ground have resulted in more, and larger, glacial lakes, increased ground instability in mountain and other regions, and led to changes in some Arctic and Antarctic ecosystems (Walker, 2007). The mountain glaciers and ice caps, as well as snow cover, are receding in most areas of the world. Both the Greenland and Antarctic ice sheets are now losing mass at increasing rates. The extent and thickness (volume) of Arctic Sea ice is declining, and lakes and rivers freeze later in the fall and melt earlier in the spring (IPCC, 2007; Allison *et al.*, 2009).

 doi:10.1016/B978-0-444-52512-3.00005-X

The main climate changes that are occurring affect the level of the oceans, precipitation, and temperature. The global sea level has increased by approximately 12–22 cm during the twentieth century, but satellite records confirm that the rate of sea level rise has now almost doubled to approximately 3.4 mm year^{-1} (IPCC, 2007; Allison *et al.*, 2009). Precipitation is highly variable and trends are more difficult to isolate, but the overall precipitation and heavy precipitation events have increased in most regions; at the same time the occurrence of drought has also been on the rise, particularly since 1970 (IPCC, 2007; Allison *et al.*, 2009). Winter temperatures have increased more rapidly than summer temperatures, and nighttime minimum temperatures have warmed faster than the daytime maxima (IPCC, 2007; Meehl *et al.*, 2007).

All climate changes will have additional impacts via changes in the ecosystem, losses in agriculture, and of genetic diversity and changes to biotic and abiotic interactions with other species and ecosystem processes. These impacts are potentially very significant in determining the effects of climate change.

Climate Change on Agriculture

Agriculture is extremely vulnerable to climate change, and global warming is already changing agriculture in some parts of the world. Higher temperatures, changing patterns of rainfall, more extreme droughts and floods, eventually reduce crop yields without discouraging weed, disease, and pest challenges. Changes in precipitation patterns increase the likelihood of short-term crop failures and long-term declines in production. Although there will be gains in some crops in some regions of the world, the overall impact of climate change on agriculture is expected to be negative, threatening global food security. All will have an impact on food production in the future (Nelson *et al.*, 2009; Smith, 2011). Moreover, the impact of climate change on agriculture has repercussions that extend far beyond the supply of food. Agriculture accounts for 29% of the gross domestic product (GDP) in developing countries and provides jobs for 65% of their populations (Smith, 2011). In this scenario, the consequences will be catastrophic, not only for farmers, but for the economy as well. Using the results from formal economic models, it is estimated that, in the absence of effective counteraction, the overall costs and risks of climate change will be equivalent to a 5% decrease in global GDP each year (Stern, 2005). If a wider range of risks and impacts is taken into account, the estimates of damage could rise to a 20% decrease in GDP or more, with a disproportionate burden on and an increased risk of famine in the poorest countries (Altieri and Koohafkan, 2003).

It is possible to isolate some critical challenges that agriculture will face from climate changes, for example, water availability. In many regions water is extremely scarce and with increasing demand, the competition for its use will increase, especially with decreasing precipitation and the river flow changes. In Asia, rainfall changes and snow melt in the glacier, probably, are the biggest threats. In Africa, many people depend directly on rain for food and livelihood, and any change in the rainfall represents a great risk. Water quality is also a problem, the saline water will increasingly affect agricultural systems due to seawater intrusion, overexploited aquifers, and unsustainable irrigation practices (Moorhead, 2009). At mid- to high latitudes, crop productivity may increase slightly for local mean temperature increases of up to 1–3 °C, depending on the crop, whereas at lower latitudes, crop productivity is projected to decrease for even relatively small local temperature increases (1–2 °C). In the tropics and subtropics in general, crop yields may fall by 10–20% by 2050 because of warming and drying, but there are places where yield losses may be much more severe.

Higher temperatures will challenge many agricultural systems. Plants are sensitive to high temperatures during critical stages such as flowering and seed development. Often combined with drought, high temperatures can mean disaster to farmers' fields. Carbon dioxide levels also have implications for crop plants, although impacts are complex and need further research.

Many pests and diseases of crops, animals, and humans are sensitive to climate, and one can expect these to change in currently unpredictable ways. Some will become prevalent in areas where they were previously unknown, when the climate becomes favorable in those areas. Natural ecosystems are equally at risk from climate change.

Smallholder and subsistence farmers, pastoralists, and artisanal fisher folk will suffer complex, localized impacts of climate change, due both to constrained adaptive capacity in many places and due to the additional impacts of other climate-related processes such as snow-pack decrease and sea level rise.

Furthermore, changes in the frequency and severity of extreme climate will have significant consequences for food production and food security; not alone the mean climate change that will have an impact. Increasing frequencies of heat stress, drought, and flooding events are estimated to be likely, even though they cannot be modeled in any satisfactory way with current levels of understanding of climate systems, but these will have adverse effects on agricultural and natural systems over and above the impacts due to changes in mean variables alone.

Many recent studies have identified environmental climate changes and stresses as major threats on food production, food quality, and global food security in the twenty-first century (Ashmore *et al.*, 2006; Atkinson *et al.*, 2008; Battisti and Naylor, 2009). One of the predictions is that the number of undernourished people would have increased by 150% in the Middle East and North Africa and by 300% in sub-Saharan Africa by the year 2080, compared with 1990 (Tubiello and Fischer, 2007). Currently, millions of hungry people subsist on what they produce. If climate change reduces production while populations increase, there is likely to be more hunger. In addition, the impacts of climate change include reductions in calorie consumption and increases child malnutrition. Thus, aggressive agricultural productivity investments are needed to raise calorie consumption enough to offset the negative impacts of climate change on the health and well-being of children (Nelson *et al.*, 2009; Ramalho *et al.*, 2009). Therefore, improving biomass production and seed yield per area under suboptimal water availability due to drought and other abiotic stresses by improving the plants themselves is now even more pressing. Food and Agriculture Organization estimates that the

current soybean worldwide production (~220 million tons) must increase by a staggering 140% to meet food demands of a growing human population by 2050 (Bruinsma, 2009).

With decreasing availability of well-watered agricultural areas, attempts to reach such future production levels will require the use of existing or new cropping areas having limited water supply (Sinclair *et al.*, 2010). Abiotic stress factors, such as drought, heat, soil salinity, tropospheric ozone, and excess UV radiation are already causing significant agricultural yield losses and will become even more prevalent in the coming decades due to the effects of global change (Ashmore *et al.*, 2006; Ortiz *et al.*, 2008; Battisti and Naylor, 2009; Feng and Kobayashi, 2009; Fuhrer, 2009; Wassmann *et al.*, 2009). For the sake of objectivity, this article will focus on drought, heat, and flooding stress.

Drought and Heat Stress

Water stress may arise as a result of two conditions, either due to excess of water or water deficit. The more common water stress encountered is the water-deficit stress known as the drought stress (Mahajan and Tuteja, 2005).

Drought is a major abiotic stress factor that affects the growth and development of plants (Harb *et al.*, 2010). It can also affect crop productivity, through insufficient rainfall or altered precipitation patterns (Toker *et al.*, 2007). Drought or soil water deficit can be chronic in climatic regions with low water availability or random and unpredictable due to changes in weather conditions during the period of plant growth. The effects of drought are expected to increase with climate change and growing water scarcity (Harb *et al.*, 2010). Drought is often accompanied by relatively high temperatures, which promote evapotranspiration and affects photosynthetic kinetics, thus intensifying the effects of drought and further reducing crop yields. Plant responses to soil water deficit have been extensively investigated at developmental, physiological, and molecular levels and the complex nature of growth regulation under stress conditions has been highlighted (Passioura, 1996; Bray, 1997; Shinozaki and Yamaguchi-Shinozaki, 2000; Harb *et al.*, 2010; Hirayama and Shinozaki, 2010). Severe water stress may result in the arrest of photosynthesis, disturbance of metabolism and finally the death of plant (Jaleel *et al.*, 2008). Water stress inhibits cell enlargement more than cell division. It reduces plant growth by affecting various physiological and biochemical processes, such as photosynthesis, respiration, translocation, ion uptake, carbohydrates, nutrient metabolism, and growth promoters (Jaleel *et al.*, 2008; Farooq *et al.*, 2008). In plants, a better understanding of the morphoanatomical and physiological basis of changes in water stress resistance could be used to select or create new varieties of crops to obtain better productivity underwater stress conditions (Nam *et al.*, 2001; Martinez *et al.*, 2007). It is also anticipated that the occurrence of drought in many food-producing regions will increase significantly in response to climate change (Collins *et al.*, 2008; Reynolds and Ortiz, 2010).

High temperature also reduces the antioxidant enzyme activities and the intensity of the reactions decrease as the plants age (Balla *et al.*, 2007). Warmer temperatures and longer growing seasons will increase crop water demand, whereas summer rainfall will remain about the same or possibly decline. Some of the drought challenges are declining and more variable yields of rain-fed crops and decline in quality of high-value fruit and vegetable crops. The solutions for drought conditions are to increase irrigation capacity, particularly for high-value crops, shift to drought-tolerant crop varieties and shift plant dates to avoid dry periods (Smith, 2011).

The reactions of plants to water stress differ significantly at various organizational levels depending on the intensity and duration of stress as well as plant species and its stage of growth (Chaves *et al.*, 2002; Jaleel *et al.*, 2008). Understanding plant responses to drought is of great importance and also a fundamental part for making the crops stress tolerant (Reddy *et al.*, 2004; Zhao *et al.*, 2008).

Flooding Stress

The man-induced world climate change will increase the frequency of precipitations of higher magnitude as well as tropical cyclone activity (IPCC, 2007). As a result, the occurrence of flooding events on flood plains (i.e., lowlands) and cultivated lands is expected to be higher (Arnell and Liu, 2001). Under flooding conditions, the water table rises above soil level and envelopes some aerial portions of the plant. Soil water excess determines a severe decrease in the oxygen diffusion rate into the soil (Ponnamperuma, 1972, 1984; Armstrong 1979). Shortly after the soil is flooded, the respiration of roots and microorganisms depletes the remnant oxygen and the environment becomes hypoxic (i.e., oxygen levels limit mitochondrial respiration) and later anoxic (i.e., respiration is completely inhibited) (Blom *et al.*, 1994; Bailey–Serres and Voesenek, 2008; Wegner, 2010).

When flooding results in complete submergence, and in normally submersed aquatic plants, availability of carbon dioxide, light, and oxygen to the shoots typically diminishes (Jackson and Ram, 2003). Plant roots suffer hypoxia or anoxia. The first constraint for plant growth under flooding is the immediate lack of oxygen necessary to sustain aerobic respiration of submerged tissues (Armstrong, 1979; Vartapetian and Jackson, 1997; Voesenek *et al.*, 2004).

Under conditions of water excess, the soil type and its features will be crucial in determining how deep the stress will influence plant development. With the reduction of the soil redox potential a range of potentially toxic compounds appear, such as sulfides, soluble Fe and Mn, ethanol, lactic acid, acetaldehyde, and acetic and formic acid, and may injure plant tissues by impairing proper cell metabolism (Kozlowski, 1997; Fiedler *et al.*, 2007). Therefore, lack of oxygen and later the accumulation of such compounds are the major constraints that plants suffer under flooding conditions. A major constraint resulting from water excess, at least for poorly adapted species, is an inadequate supply of oxygen to submerged tissues; diffusion of oxygen through water is 104-fold slower than in air (Armstrong and Drew, 2002). In addition to the oxygen deficiency, excess water also leads to other changes in the soil that influence levels the hormones ethylene in the plants (Smith and Russell, 1969; Jackson, 1982).

Soil waterlogging and submergence are abiotic stresses that influence species composition and productivity in numerous plant communities. In rice farming, flooding regimes are manipulated (e.g., paddy rice) or are accommodated by genotype selection (e.g., deepwater rice) to secure much of the world's production of this staple crop (Grist, 1986). There have also been recent advances toward developing cultivars for lowland areas prone to short duration flash flooding (Siangliw *et al.*, 2003; Toojinda *et al.*, 2003). For most other crops, excess water is a major constraint to productivity in many regions and situations (Jackson, 2004), adversely affecting grain yields (Setter and Waters, 2003) and growth of pasture species (Gibberd and Cocks, 1997; Gibberd *et al.*, 2001).

The concentrations of oxygen (O_2), CO_2, reactive oxygen species (ROS), and ethylene change upon flooding and can occur in various combinations, as determined by the flooding regime. Tolerant plant species exploit the escape strategy based on a suite of (inducible) morphological and anatomical traits allowing reaeration of flooded tissues by the formation of aerenchyma; or those that adopt a quiescence strategy composed of traits that conserve the use of energy and carbohydrates to prolong underwater survival (Bailey–Serres and Voesenek, 2008; Colmer and Voesenek, 2009).

Responses and Adaptation of Plants to Climate Change

Increasingly erratic rainfall and extreme weather events can affect growth and development of plants, influencing the physiology, behavior, abundance, and distribution of many species. Plants are invariably intolerant to the current major abiotic stresses (that are likely to be further aggravated by climate change, such as drought, submergence, and salinity). These stresses reduce yields in millions of hectares in production areas that have had impact. Tolerance to abiotic stresses is very complex, due to the intricate interactions between stress factors and various molecular, biochemical, and physiological phenomena affecting plant growth and development (Razmjoo *et al.*, 2008). Agricultural yield losses due to abiotic environmental stresses are obvious and have been well documented (Mackill *et al.*, 2010).

Plants are sessile organisms that cannot escape from environmental constraints and, as a result, have evolved numerous adaptive responses to cope with environmental stresses. Stress is an altered physiological condition caused by factors that tend to disrupt the equilibrium. Strain is any physical and chemical change produced by a stress (Gaspar *et al.*, 2002). Stress being a constraint or highly unpredictable fluctuations imposed on regular metabolic patterns cause injury, disease, or aberrant physiology. Plants are frequently exposed to many stresses, such as drought, low temperature, salt, flooding, heat, oxidative stress, and heavy metal toxicity, while growing in nature, caused principally by environmental stresses (Jaleel *et al.*, 2009).

Drought and flooding can cause serious constraints to production. Effects of drought stress change the morphological characteristics. It has been established that drought stress is a very important limiting factor at the initial phase of plant growth and establishment. It affects both elongation and expansion growth and also affects the yield, but the tolerance of any species to this menace varies remarkably (Anjum *et al.*, 2003; Bhatt and Srinivasa, 2005; Kusaka *et al.*, 2005; Shao *et al.*, 2008). A ramified root system has been implicated in the drought tolerance and high biomass production primarily due to its ability to extract more water from soil and its transport to the above-ground parts for photosynthesis. In addition to other factors, changes in photosynthetic pigments are of paramount importance to drought tolerance (Jaleel *et al.*, 2009).

Other very important effects from climate change are the excess rainfall that will increase the frequency of precipitation of higher magnitude as well as tropical cyclone activity that cause stress for flooding. Those natural disturbances affect crop and forage production worldwide (Bailey–Serres and Voesenek, 2008; Colmer and Voesenek, 2009). Plants develop a suite of anatomical, morphological, and physiological responses in order to deal with partial submergence imposed by flooding (Armstrong, 1979; Kozlowski and Pallardy, 1984; Vartapetian and Jackson, 1997; Striker *et al.*, 2005; Colmer and Voesenek, 2009).

The most common anatomical response is the generation of aerenchyma in tissues, which facilitates the transport of oxygen from shoots to roots (Justin and Armstrong, 1987; Seago *et al.*, 2005; Colmer, 2003). At the morphological level, usual responses to flooding include adventitious rooting and increases in plant height and consequently, in the proportion of biomass above water level (Naidoo and Mundree, 1993; Grimoldi *et al.*, 1999). This also helps to facilitate the oxygenation of submerged tissues through the aerenchyma tissue (Laan *et al.*, 1990; Colmer, 2003). At the physiological level, flooding modifies water relations and carbon fixation in plants. Closing of stomata, with or without leaf dehydration, reduction of transpiration, and inhibition of photosynthesis are responses that can occur in hours or days, depending on the tolerance to flooding of each plant species (Bradford and Hsiao, 1982; Else *et al.*, 1995; Insausti *et al.*, 2001; Striker *et al.*, 2005; Mollard *et al.*, 2008, 2010).

Plant species can also adjust to these novel climate conditions through phenotypic plasticity, that is the range of phenotypes a single genotype can express as a function of its environment, or adapt through natural selection or migrate to follow conditions to which they are adapted; these options are not mutually exclusive, that is, the capacity of a given plant to alter its physiology, morphology, or phenology and allows it to tolerate, avoid, or escape a certain stress condition (Nicotra *et al.*, 2010; Grime *et al.*, 1986). The phenotypic plasticity is understood to be genetically controlled, heritable, and of potential importance to species evolution (Bradshaw, 2006; Lande, 2009). With mounting evidence from molecular and developmental biology, the understanding of the mechanisms of plasticity, which will be crucial for predicting changes in species distributions, community composition, and crop productivity under climate change will be easier (Van Kleunen *et al.*, 2007; Van Kleunen and Fischer, 2001).

Biotechnology Tools in the Breeding for Climate Change

As a complement to changes in agronomic management, plant breeding is a convenient technological response to

environmental challenges (Yadav *et al.*, 2011), but considerable time and investment is required to deliver changes in the productivity or quality of varieties. The genetic basis of adaptation to environments is complex, and it is difficult to unravel what sets of genes are required for optimal performance and to explain the interactions of genes controlling any given trait. Investment in plant breeding requires assessment of when and where this is the most economical response for an industry in dealing with climate change (Chapman *et al.*, 2012).

Biotechnology techniques can help to accelerate the improvement of performance under harsh environmental conditions, particularly because breeding for abiotic stress tolerance sometimes has linkage drag issues, i.e., undesirable genes are also transferred along with desirable traits; and also because reproductive barriers limit the transfer of favorable alleles from diverse genetic resources. For instance, advances in genomics coupled with bioinformatics and stress biology can provide useful genes or alleles for conferring stress tolerance. Two biotechnology approaches have a key role in this work, the molecular breeding (MB) and genetic engineering (GE), and their integration with conventional breeding to develop crops that are more tolerant of abiotic stresses (Varshney *et al.*, 2011).

Molecular Breeding

The detection and exploitation of genetic variation have always been an integral part of plant breeding. DNA-based molecular markers are useful for detecting the genetic variation available in germplasm collections and breeding lines. During the past two decades, many different molecular markers have been developed for most major crop species. These markers have been used extensively for the development of saturated molecular genetic and physical maps and for the identification of genes or quantitative trait loci (QTLs) controlling traits of economic importance for marker-assisted selection (MAS) (Varshney *et al.*, 2009). Despite the great collaboration performed by molecular markers, the genomics-assisted breeding approaches have greatly advanced with the increasing of genome and transcriptome sequence data for several model plant and crop species, such as rice (IRGSP, 2005), poplar (Tuskan *et al.*, 2006), sorghum (Paterson *et al.*, 2012), maize (Schnable *et al.*, 2009), and soybean (Schmutz *et al.*, 2010).

The MB approach involves first identifying QTLs or genes for traits of interest, such as tolerance to abiotic stresses, after identifying the markers associated with QTLs or genes; the candidates can be introgressed in elite lines through marker-assisted backcrossing (MABC). For two most important abiotic stress, heat and drought, some QTLs for tolerance were identified in important crops, such as wheat rice and maize (Paliwal *et al.*, 2012; Changrong *et al.*, 2012; Almeida *et al.*, 2013).

There are two general approaches to understand the function of a gene: forward genetics and reverse genetics (Alberts *et al.*, 2007). Reverse genetics is a particular approach in discovering the function of a gene. It begins with a well-characterized phenotype and works toward identifying the gene(s) responsible for the phenotype. Genetic mapping approaches, such as QTL mapping and association mapping, are part of forward genetics and are often used because gene transfer is not required (Tierney and Lamour, 2005; White *et al.*, 2007).

QTL mapping can be defined as the marker-aided genetic dissection of variation of complex phenotypes in segregating progenies. The objectives of QTL mapping analysis are: to provide knowledge toward fundamental understanding of individual gene and interactions, enable positional cloning, and improve breeding value estimates and selection response through MAS in plants and animals (Holland, 2004; Collard *et al.*, 2005).

Anticipated changes in climate and its variability, particularly extreme temperatures and changes in rainfall, are expected to make crop improvement even more crucial for food production (Varshney *et al.*, 2011). The objective of plant breeding for stressing environments is to accumulate favorable alleles that contribute to stress tolerance in a plant genome. Genes that confer stress resistance can be sourced from germplasm collections, including wild relatives of crops that are held in genebanks or organisms that currently live in habitats of water deficit or excess, extreme temperature, and salinity conditions and have evolved to cope with such conditions (Nevo and Chen, 2010). Thus, the genetic variation for stress tolerance is the engine that drives advances in plant breeding (Fridman and Zamir, 2012).

The abiotic stress is considered one of the most important factors affecting yield all over the world, mainly those stress provoked by climate changes, such as drought, heat, and flooding. The detection and genetic location of tolerance gene candidates and QTL for these stresses, together with the development of molecular markers, linkage maps, and genetic association studies have largely contributed to the purpose. There exists a vast array of gene for tolerance abiotic stress in several crops and studies using QTL mapping approaches and the major QTLs/candidate genes have been widely described.

Quantitative Trait Loci Mapping for Drought and Heat Stress

Drought and heat are the most significant environmental stresses in agriculture worldwide and improving yield under these conditions is a major goal of plant breeding. Identification of genetic factors involved in plant responses to drought stress will provide a solid foundation to improve drought and heat tolerance. To achieve progress in plant yield in drought-prone environments, it is necessary to develop new tools to understand the complex network of drought-related and heat-related traits. Molecular genetic approaches have uncovered many QTLs affecting yield under drought and heat or the expression of abiotic stress tolerance-related traits. Across many species, upon water stress by drought, the accumulation of biomass increases the root/shoot ratio (Sharp and Davies, 1989).

QTLs studies with recombinant inbred lines (RILs) and near-isogenic lines identified several genomic regions associated with resistance to preflowering and postflowering drought stress in sorghum. Four genomic regions associated with the stay-green trait were identified using a RIL population developed from B35 × Tx7000. These four major stay-green QTLs

were consistently identified in all field trials and accounted for 53.5% of the phenotypic variance (Sanchez *et al.*, 2002).

The mapping population Bala × Azucena RILs (Price *et al.*, 2000) was used to identify QTLs for drought avoidance in rice. A total of 15 clusters of QTLs for drought avoidance were detected (Khowaja *et al.*, 2009). Although QTLs were found on chromosomes 1, 3, 4, 5, 6, 7, 8, 10, and 12, the major gene clusters were found on chromosomes 3, 6, and 7. From these, for only three drought meta-QTLs, deeper root systems may be explaining drought avoidance. The complex regulation mechanisms and the large number of regions associated with drought avoidance point out that further investigations are still needed to better understand the genetic basis of this trait. Moreover in rice, a QTL on chromosome 12 was detected in a large population from the cross of Vandana/Way Rarem that accounted for approximately 50% of the genetic variance, and was expressed consistently over 2 years (Bernier *et al.*, 2007). This QTL seems to be related to increased water uptake of plants under stress (Bernier *et al.*, 2009). A chromosome 3 QTL had a large effect on drought tolerance in the cross between the tolerant variety Apo and the widely grown susceptible variety Swarna (Venuprasad *et al.*, 2009). This is a very promising QTL for use in MAS, because the variety Swarna is widely grown in drought-prone environments due to its high yield and other desirable traits. QTLs for grain yield under drought stress have been mapped in many rice populations (Babu *et al.*, 2003; Lafitte *et al.*, 2004; Lanceras *et al.*, 2004; Bernier *et al.*, 2007; Kumar *et al.*, 2004). Despite large efforts, no successful application in marker-assisted breeding (MAB) has been yet accomplished. So far, repeatability problems and the complex nature of gene interactions involved in drought response suggest that further investigations are needed to better understand the genetic basis of this trait (Swamy *et al.*, 2011).

High temperature (>30 °C) at the time of grain filling is one of the major causes of yield reduction in wheat. To identify QTLs for heat tolerance under terminal heat stress, a set of 148 RILs were developed by crossing a heat-tolerant hexaploid wheat (*Triticum aestivum* L.) cultivar (NW1014) and a heat-susceptible (HUW468) cultivar. The F5, F6, and F7 generations were evaluated in two different sowing dates under field conditions for 2 years. Three QTLs that explained the phenotypic variation were identified and can be used in MAS for heat stress in wheat (Paliwal *et al.*, 2012).

Quantitative Trait Loci Mapping for Flooding Stress

Rising temperatures due to the accumulation of GHGs are expected to result in declining crop yields. One of the abiotic stresses that are anticipated to worsen as the consequence of climate change is flooding or waterlogging stress. Therefore, submergence tolerance is an important trait where short-term 'flash' flooding damages crops. Flooding causes a reduction of oxygen supply and inhibiting respiration. Highly tolerant varieties such as FR13A from Orissa, India, have been used in breeding programs (Vergara and Mazaredo, 1975; Hille-RisLambers and Vergara, 1982; Mackill *et al.*, 1993). Tolerance in these varieties is controlled by the *Sub1* locus on chromosome 9 (Xu and Mackill, 1996). This major QTL has been cloned and successfully transferred to cultivated rice genotypes, *Submergence1* (*Sub1*) (Xu *et al.*, 2006). A cluster of three genes, *Sub1A*, *Sub1B*, and *Sub1C*, which encode putative ethylene responsive factors (ERFs) were found to be associated with the phenotype, but a major effect of *Sub1A-1* was observed after its overexpression (Xu *et al.*, 2006). Another QTL was mapped in the cross C9285 (deepwater rice) × Taichung 65 (Hattori *et al.*, 2009). Two genes on chromosome 12 (*Snorkel1-SK1* and *Snorkel2-SK2*), which possess a putative nuclear localization signal and a single APETALA2/ERF domain were described. The ERF domains are very similar to those of *Arabidopsis thaliana* ERF1, *O. sativa* ERF1, and SUB1A-1. A comparison between the effects of SK1 and SK2 showed that the latter is more effective at internode elongation in water. Some other common QTL related to flooding have been found in rice (Kamoshita *et al.*, 2002; Zheng *et al.*, 2003, 2008; Zheng, 2006). They include regions near markers RM315 (C1), RZ 318 (C2), between RM338 and RZ284 (C3), near RZ70 (C5), and on the telomeric region (C9). Several of these QTLs have been mapped closely or together with root trait QTLs when well drained and drought conditions were compared.
